ABSTRACT

The current assessment represents the initial attempt to conduct an analytical assessment of the Georges Bank winter flounder stock. The Georges Bank population of winter flounder is a discrete offshore stock distributed in the shallower areas of the bank complex. The stock is exploited by both directed otter trawl fisheries and as bycatch in large and small mesh otter trawl and scallop dredge fisheries targeting other species. Recent management measures have been directed at other principal groundfish species or the entire groundfish complex, but management actions including seasonal and year round area closures, mesh size restrictions, effort controls, and retention restrictions on specific gear sectors likely have a significant effect on the Georges Bank winter flounder resource.

The Georges Bank winter flounder stock has been exploited by U.S., Canada, and distant water fleets historically, but the U.S. fishery has generated most of the reported landings since 1970. Landings during the 1970s and 1980s ranged between 2,000 and 4,000 mt, but declined to approximately 1,700 mt in 1993. Otter trawl gear accounts for greater than 95% of landings in most years, although the proportion of landings from the scallop dredge sector increased in the early 1990s. Discards are known to occur in both the otter trawl and scallop dredge fisheries. Although available data were inadequate to either estimate the magnitude of discards or characterize their size or age distribution, information from sea sampling observations indicates that discards are a relatively low proportion of the total catch in the otter trawl fishery.

Landings per unit effort indices for all trips landing winter flounder and directed trips declined between the mid-1970s and early 1990s. U.S. and Canadian research vessel survey indices are highly variable, but appear to indicate a significant decline in abundance and biomass between the early 1980s and early 1990s.

A Virtual Population Analysis calibrated with research vessel survey indices indicates strong year classes in 1980 (8.2 million), 1985 (6.6 million), 1987 (7.4 million), and 1994 (5.4 million) based on age 2 recruitment numbers. Spawning stock biomass declined from 8,300 mt in 1982 to 2,000 mt in 1994 and has increased to 3,500 mt in 1997. There is little apparent relationship between stock and recruitment. Age 2 recruitment from the 1995 and 1996 year classes is poor, and the 1996 year class (0.77 million) is the weakest in the time series. The average fishing mortality rate (ages 4-6, unweighted) increased from approximately 0.5 in 1982 to above 1.0 in 1984, and ranged between 0.66 and 1.36 in the mid-1980s to early 1990s. The fishing mortality rate declined to below 0.5 in 1994 and has ranged between 0.32 and 0.53 through 1997.

A yield per recruit analysis estimates $F_{0.1} = 0.21$ and $F_{\max} = 0.42$, and an SSB per recruit analysis estimates $F_{20\%} = 0.47$. An unconstrained surplus production analysis estimates MSY as 3,100 mt and the stock biomass at MSY (B_{MSY}) of 11,400 mt. The Sustainable Fishery Act (SFA) harvest control rule was re-estimated and at the current biomass proxy, the corresponding fully recruited threshold and target fishing mortality rates are 0.04 and 0.03, respectively. Relative to the SFA harvest control rule, the stock was in an overfished condition and overfishing was occurring ($F_{1998} = 0.34$). Short-term stochastic projections indicated that SSB will increase slightly (3%) between 1999 and 2000 if the stock is fished at $F_{20\%} = 0.47$ in 1999, and increase between 13% ($F_{1998} = 0.34$) and 44% ($F = 0.00$) if fished at lower levels.

INTRODUCTION

Georges Bank winter flounder (*Pseudopleuronectes americanus*) is a demersal flatfish species distributed in the Northwest Atlantic from Labrador to Georgia (Bigelow and Schroeder 1953, Klein-MacPhee 1978). Although primarily distribution in shallow inshore waters where estuarine habitat serves as important spawning and nursery areas, winter flounder are also distributed on some shallow offshore banks including Nantucket Shoals and Georges Bank principally in waters shallower than 80 m in depth. Adult winter flounder feed primarily on benthic invertebrates including annelids (predominately polychaetes), Cnidarids, and Anthozoa (Langton and Bowman 1981). Principal predators include striped bass (*Morone saxatilis*), bluefish (*Pomatomus saltatrix*), goosefish (*Lophius americanus*), spiny dogfish (*Squalus acanthias*), and sea raven (*Hemitripterus americanus*) (Dickie and McCracken 1955, Grosslein and Azarowitz 1982). Spawning peaks on Georges Bank during March and April, as evidenced by the presence of spawning condition fish in the Northeast Fisheries Science Center (NEFSC) Spring research vessel bottom trawl survey and high densities of eggs and larvae detected by NEFSC ichthyoplankton surveys.

Stock Structure

Evidence from tagging data, differences in life history characteristics, and meristic studies provide evidence for discrete stocks of winter flounder in the U.S. waters of the Northwest Atlantic. Winter flounder on Georges Bank have considerably higher growth rates than fish from inshore waters (Bigelow and Shroeder 1953, Lux 1973); and historically, the Georges Bank stock was considered as a separate species (*Pseudopleuronectes dignabilis*; Kendall 1912). Meristic studies indicate that fin ray counts differ for fish from Georges Bank and inshore areas indicating further evidence for a discrete offshore stock of winter flounder on Georges Bank (Perlmuter 1947, Lux *et al.* 1970). Extensive tagging studies of winter flounder indicate little mixing of fish between Georges Bank and inshore areas (Coates *et al.* 1970, Howe and Coates 1975), providing further evidence for discrete stock structure (Pierce and Howe 1977).

For the purposes of this assessment, the Georges Bank stock was defined to include U.S. statistical areas 522-525, 551, 552, 561, and 562 (Figure 1) which corresponds approximately to NAFO subarea 5Zh,j,m&n. Corresponding survey data include NEFSC offshore survey strata 01130 to 01220. NEFSC offshore strata 01230 appears to include a mix of winter flounder from the Southern New England/Mid Atlantic stock complex and the Georges Bank stock, and therefore was not included in survey analyses for this assessment. Canadian survey strata include strata 5Z1 to 5Z8.

Fishery Description

Winter flounder, also known as blackback or lemon sole within the commercial fishery sector, are harvested primarily using otter trawl gear, and landings occur in both targeted landings and as bycatch in fisheries targeting other species. Bycatch landings and discards occur in trawl fisheries targeting other groundfish species and scallop dredge fisheries. Although recreational landings are a significant source of fishing mortality in inshore waters for the Southern New England stock complex, recreational landings from the Georges Bank stock are insignificant and are not included in this assessment.

Management History

Over the past 25 years, management of the commercial fishery for Georges Bank winter flounder has focused on minimum size limits and management measures (seasonal and year round area closures, mesh size regulations, effort control measures, and fleet capacity reduction programs) primarily intended to address management needs for other demersal species (Atlantic cod, haddock, and yellowtail flounder). Seasonal spawning closures of haddock spawning grounds, which increased in temporal and spatial coverage since their inception in 1970 (Clark 1976), have provided some measure of protection for the winter flounder stock.

Winter flounder was included in the New England Fishery Management Council's Atlantic Groundfish Fishery Management Plan (1977-1982). This initial plan established a minimum commercial size limit (11 inches, 28 cm), imposed minimum mesh sizes for trawls, and established spawning stock biomass per recruit targets. In 1982, the Council adopted an Interim Groundfish Plan, which established a minimum mesh size of 130 mm (5 1/8"). In 1983, the minimum mesh size was increased to 140 mm (5.5") In 1986, the Council's Multispecies Fishery Management Plan increased the minimum legal size to 30 cm (12 in) and imposed seasonal area closures. Amendments 5 and 7 (1994, 1996), established effort controls (days at sea limits), further increased minimum mesh size to 142 mm (6" diamond or square mesh), imposed trip limits for regulated groundfish bycatch in the sea scallop fishery, and prohibited small mesh fisheries from landing regulated groundfish. In December 1994, two large areas on Georges Bank were closed to fishing on a year round basis to protect overfished groundfish species. These areas include both the eastern and western edges of the distribution of winter flounder on the bank.

Amendment #9 to the Multispecies Fishery Management Plan was submitted in 1998 to revise the overfishing definition according to Sustainable Fisheries Act requirements. The Overfishing Definition Review Panel (Applegate *et al.* 1998) recommended an MSY based control rule derived from survey based proxies of MSY reference points. Biomass reference points were based on the U.S. NEFSC Autumn research vessel biomass index (stratified mean kg/tow) and fishing mortality reference points were based on an exploitation index (catch/U.S. NEFSC Autumn research vessel biomass index).

Georges Bank winter flounder was previously assessed in 1978 (Lange and Lux 1978) and 1986 (Gabriel and Foster 1986). These two assessments provided descriptive summaries of catch, effort, survey indices, and yield per recruit modeling. The current assessment represents the initial attempt to conduct an analytical assessment of the stock.

THE FISHERY

Commercial Landings

Before 1976, commercial landings of Georges Bank winter flounder were reported from the United States, Canada, and distant water fleets including the former Soviet Union. From 1964 to 1971, commercial landings increased, reaching a peak of 4,500 mt in 1972 (Figure 2, Table 1). Landings declined from 1971 to 1976, before increasing sharply to 3,600 mt in 1977. Commercial landings peaked between 1980 and 1984 (averaging 3,800 mt/year), but declined sharply beginning in 1985 (Figure 2). Landings trended downward after 1984, with the

exception of increased landings resulting from the strong 1984 year class in 1987 and 1988. Commercial landings in 1995 (760 mt) were the lowest recorded in the landings time series dating back to 1962.

Since the late 1960's, U.S. landings have been the dominate component of total commercial landings. Canadian landings have averaged 0.1% to 2.7% of total fishery landings since 1970. The Canadian industry's interest in the Georges Bank winter flounder resource has increased (S. Gavaris, personal communication), and reported Canadian landings in 1997 reached their highest reported levels since 1966 (Table 1).

Otter trawls have been the dominate gear accounting for greater than 98% of landings in the U.S. fishery through 1985 (Table 2). Since 1985, the proportion of landings taken by scallop dredges has increased steadily from less than 1% to approximately 7 to 8% by the early 1990s. It is unclear whether this trend represents increased retention rates by the scalloper, or improved reporting of non-target landings by the fleet. The proportion of winter flounder landings accounted for by scallop dredges declined from 1994 to 1997 in response to U.S. groundfish retention limits imposed in the scallop fishery. Tonnage class 3 (51-150 GRT) otter trawlers generally account for approximately 60% to 80% of U.S. landings, while tonnage class 4 (151-500 GRT) otter trawlers generally account for all but a few percent of the remaining U.S. landings (Table 3).

Commercial landings since 1982 are reported for 8 market categories (lemon sole, extra large, large, large/mixed, medium, small, peewee, and unclassified) based primarily on the individual fish size. Three categories (lemon sole, small, and large) comprised approximately 85% of the commercial landings from 1982 to 1997 (Table 4).

Commercial Discards

Commercial discarding occurs in the otter trawl and scallop gear sectors due to marketability (size and condition), minimum size limit regulations, and groundfish retention limits which prohibit groundfish retention in some small mesh fisheries and restrict retention in others (scallop fishery). Discard information is available from two primary sources, the sea sampling database which summarizes information collected by trained observers riding on commercial trips and the Vessel Trip Report (VTR) database which contains records of commercial operator reported discards.

Sea sampling data (available 1989 to 1997) represents the most reliable source of information available for estimating commercial discards. The total number of Georges Bank trips where winter flounder weights were collected ranged from 4 to 17 trips annually. Sea sampling of scallop dredge trips was limited with no more than 5 trips available annually where weights of landed and discarded winter flounder were sampled. Based on this limited amount of information, estimated total discards in the trawl gear sector ranged from 1.2 to 24.9 mt annually, representing 0.2 to 1.6% of otter trawl catch. Limited sampling of sea scallop trips precludes even preliminary estimates of discards for this fleet sector. However, limited sea sampled trips

occurring in 1995 to 1997 (eight trips) appear to indicate that discarding of winter flounder by this gear sector may have increased significantly in response to groundfish retention regulations.

Length frequency information available in the sea sampling database was examined to determine the feasibility of partitioning discard weight estimates into numbers at length. The number of discarded winter flounder measured annually by the Sea Sampling Program ranged from 70 in 1989 to none in 1997. Clearly, the number of discarded winter flounder measured was insufficient to characterize the overall length frequency distribution of the discarded portion of the catch. The number of discarded winter flounder measured in the scallop dredge gear sector was insignificant in every year except 1997, when 239 discarded winter flounder were measured in the second quarter and a total of 274 were measured across all quarters. Based on the limited data available to either estimate the magnitude of total discards or characterize their size distribution, we concluded that it would be inappropriate to generate estimates of discards based on an analysis of available sea sampling data.

Commercial operator reported discards in the VTR database (available 2nd Quarter of 1994 to 1997) represented the next best available source for estimating discards. Reporting rates in the VTR database are known to be incomplete because many operators fail to reliably report discards. To avoid problems associated with incomplete reporting, we estimated discard ratios using VTR data based on a subset of logbook records that reported at least 1 pound of discards for any species (DeLong *et al.* 1997, NEFSC 1997, Brown and Munroe 2000). By using this subset to characterize discard ratios, we made three basic assumptions: 1) it is highly unlikely that a groundfish trip could operate within the Georges Bank stock area without generating discards of some species, 2) trips that reported discards of some species reliably reported discards of winter flounder, and 3) the ratio of landed to discarded weight from this subset was representative of the discarding behavior of the entire fleet. Thus, the subset used to estimate discard ratios included 1) trips reporting both landings and discards of winter flounder, 2) trips reporting winter flounder discards but no landings, and 3) trips reporting winter flounder landings and discards for some other species.

For the otter trawl gear sector, the number of trips included in the discard ratio estimate ranged from 73 to 182 trips annually. Based on logbook reported discards, estimated total discards in the trawl gear sector ranged from 7.2 to 21.9 mt annually, representing 0.5 to 3.0% of otter trawl landings. Based on the number of scallop dredge trips reporting discards of winter flounder, it was clear that discard reporting rates for winter flounder are extremely low in this gear sector. From a regulatory standpoint, there are a number of disincentives to accurately reporting groundfish bycatch by scallop dredges. The limited number of trips reporting discards represent a significant source of uncertainty relative to the total fishery removals from the stock.

The third approach attempted to estimating discards involved using a combination of commercial sea sample data and research vessel survey data to estimate the total numbers discarded at length (following Mayo *et al.* 1992). Three significant weaknesses were encountered that precluded the use of this approach. First, the length frequency distribution from a research vessel survey is assumed to be representative of the size distribution of the winter flounder resource seasonally.

The limited number of strata and tows made on the U.S. NEFSC Spring and Autumn research vessel surveys produce limited numbers of winter flounder to characterize the length frequency distribution. For the period when the catch at age was produced for this assessment (1982 to 1997), the total number of winter flounder captured in representative tows during NEFSC Spring research vessel surveys ranged from 31 to 256 fish, and in 7 of the 17 years the total number of fish captured was less than 70 fish. For the U.S. NEFSC Autumn research vessel survey, the total number of winter flounder captured ranged from 12 to 320 fish, and in 8 of the 17 years the total number of fish captured was less than 70 fish. The low numbers of fish sampled result in an increased likelihood that there are some seasons when the U.S. NEFSC survey performs poorly in representing the length frequency distribution of the resource.

Second, the discard length frequency information available from sea sampling was limited resulting in a potentially poor determination of the discard selectivity ogive used in the analysis. One diagnostic for determining the performance of this estimation method is examination of the relationship between the research vessel bottom trawl survey number per tow discarded and the sea sample estimated number discarded. The expectation of is that this relationship will have a positive slope and that the correlation will be positive. The correlations between these estimated variables were weak, and in some cases negative, ranging from -0.1 to 0.7. This diagnostic indicates a significant problem with one of the inputs to this discard estimation procedure.

Third, if the number discarded at length could be reliably estimated, the number of age determinations for smaller size winter flounder from survey data is limited. While commercial age data could be used to augment age keys for older individuals, research vessel survey and sea sampling data are the only source of age determinations for sub-legal size fish. The number of survey ages available ranged as low as 12 determinations (U.S. NEFSC Autumn 1991 survey) when every winter flounder captured within the strata set was aged.

In summary, available survey, vessel trip record, and sea sampling data were insufficient to produce reliable estimates of the magnitude or age composition of winter flounder discards occurring in the Georges Bank otter trawl or scallop dredge fisheries. However, both the sea sampling and vessel trip record approaches produced consistent information concerning the magnitude of discards occurring in the otter trawl and scallop dredge fisheries. Both approaches produced low estimates of discards relative to landings (Sea Sample: 0.2% to 1.6%; VTR: 0.5 to 3.0%) for the otter trawl fishery.

In addition, both data sources appear to indicate that discarding increased in the scallop dredge fishery following the implementation of groundfish retention limits. The recent scallop dredge discards represent a significant source of uncertainty relative to the total fishery removals from this stock. However, an analysis of the spatial overlap of exploitable scallop resources and winter flounder distributions indicated little spatial overlap. Because of the uncertainty in both the underlying data and the performance of the discard estimation approaches, no commercial discards were included in the catch at age analyzed in this assessment.

Sampling Intensity of Commercial Landings

Although the U.S. commercial landings of Georges Bank winter flounder are reported for 8 market categories (lemon sole, extra large, large/mixed, large, medium, small, peewee, and unclassified), three categories (lemon sole, small, and large) comprised 85% of the commercial landings from 1982 to 1997 (Table 4). After comparing the length frequencies by market categories across years, other market categories including peewee (5.9%), medium (1.7%), extra large (0.6%) and large/mixed (0.2%) were combined with the small, large, and lemon sole market categories to estimate catch at age (see Table 5 for details). U.S. commercial length samples were aggregated by quarter and combined market categories and summarized in Table 5. Since 1982, annual sampling intensity by combined market category ranged from 36 to 902 mt of landings/sample. Sampling intensity has been lower for lemon sole than for small or large combined market categories, and sampling in all market categories deteriorated after 1992. Poor sampling intensity prior to 1982 precludes extension of the landings at age time series prior to 1982. There is no formal commercial sampling program for Canadian landings of Georges Bank winter flounder.

Landings at Age

Age composition of the 1982 to 1997 commercial landings from Georges Bank was estimated by applying commercial age-length keys to quarterly commercial numbers at length, aggregated by market category. In some instances, the landings at age analysis was pooled to half year, and in one case across three quarters of the calendar year (1993, quarters 2-4) because of insufficient length frequency sampling (Table 6). Mean weights at age were estimated by applying the length-weight equations to the quarterly length frequency samples by market category. Total numbers landed per quarter were estimated by applying the mean weights to the quarterly landings by market category and prorating according to the sample length frequency. Numbers at age were summed over market category for each quarter and annual estimates of landings at age were obtained by summing values over quarters. Landings from both the unclassified market category for U.S. landings and total reported Canadian landings were assumed to have the same age composition as the sampled U.S. landings, and the estimated landings at age was adjusted to incorporate these landings. The unsampled portion of landings generally accounted for less than 10% of the total landings at age.

Total estimated landings at age for 1982 to 1997 are summarized in Table 7A. Age 2 to 4 fish dominate landings in most years, and two relatively large year classes (1985, 1987) appear to track well through the landings at age matrix. Landings of age 1 fish are insignificant except in 1995 when almost 264,000 age 1 fish were estimated. Examination of the U.S. commercial samples indicated that large numbers of age 1 fish were present in multiple samples occurring in the third and fourth quarters of 1995. In addition, relatively large numbers of the 1994 cohort were landed as age 2 fish in 1996 and age 3 fish in 1997. Estimated landed weight (mt) of Georges Bank winter flounder by age and year is summarized in Table 7B.

Mean Weights at Age

Mean length and weight at age from the analysis of total landings at age are summarized in Tables 7C and 7D, respectively. Mean weights at age have remained relatively stable from 1982

to 1997, although poor sampling of older ages results in some variability in the estimated length and weight for ages 7 and older.

STOCK ABUNDANCE AND BIOMASS INDICES

U.S. Landings per Unit Effort (LPUE) Indices

Landings per unit effort (landings/days fished) were tabulated from the weight database by tonnage class from 1964 to 1993 for all otter trawl trips landing winter flounder and for directed trips (trips with $\geq 50\%$ winter flounder landings). Landings per unit effort indices for all trips and for directed winter flounder trips demonstrated similar trends with high levels of landings per unit effort in the 1980s, and declines in both indices to their lowest levels in the time period in the early 1990s (Figure 3).

U.S. NEFSC Research Vessel Bottom Trawl Survey

The Northeast Fisheries Science Center of the U.S. National Marine Fisheries Service has conducted a stratified random bottom trawl survey designed to assess the abundance and biomass of fish species along the continental shelf of the United States from the Scotian Shelf to Cape Hatteras since 1963 (Azarowitz 1981, Depres *et al.* 1988, Azarowitz *et al.* 1997). Two stratified random bottom trawl surveys, a spring survey (April 1968-1998) and an autumn survey (October 1963-1997) are used to estimate changes in abundance (stratified mean number/tow) and biomass (stratified mean weight (kg)/tow) of demersal fish species including winter flounder in the Georges Bank area. The indices for Georges Bank winter flounder include data from representative tows occurring in the NEFSC offshore strata 01130 to 01220. Significant changes in the catchability of winter flounder due to a door gear change in 1995 necessitated adjusting pre-1995 using door standardization coefficients (1.46 numbers, 1.39 weight; Forrester *et al.* 1997) estimated through fishing power experiments. These experiments indicated no significant differences in the catchability of winter flounder between the two research vessels (Delaware II and Albatross IV) during the survey time series.

Standardized, stratified abundance and biomass indices for Georges Bank winter flounder from the U.S. NEFSC Spring and Autumn research vessel Bottom Trawl surveys are shown in Table 8 and Figure 4. Abundance and biomass indices exhibit considerable variability but generally exhibit intermediate levels of abundance from the early 1960s to early 1980s, and declining levels of abundance since the mid-1980s (Figure 4). Both surveys have exhibited a declining trend over the final two years of the survey. The stratified mean length (cm) in both the U.S. NEFSC Spring and Autumn surveys exhibited a general declining trend between the mid 1960s and early 1990s, but the stratified mean length of winter flounder captured in the survey has increased over the past five years (Figure 5). Sharp single year declines in mean length generally correspond to the recruitment of above average year classes to the survey gear.

Stratified mean number at age for the U.S. NEFSC Spring and Autumn surveys is shown in Tables 9A and 9B, respectively. Although these indices are noisy, larger cohorts appear to track through the numbers at age matrix for the 1980, 1985, 1987, and 1994 cohorts.

Canadian Research Vessel Bottom Trawl Survey

The Department of Fisheries and Oceans, Canada has conducted a stratified random bottom trawl survey on Georges Bank since 1986. The Canadian survey, normally conducted during February or early March, occupies stations in both U.S. and Canadian waters. Station density is generally higher than on U.S. NEFSC surveys of Georges Bank. For the purposes of this assessment, stations occurring in strata 5Z1 to 5Z8 within the NAFO area 5Zh,j,m,n were included in the estimation of abundance indices. Weight data were collected, but were unavailable for estimating biomass indices (kg/tow). Stratified mean numbers/tow at length were available for winter flounder from 1987 to 1998. Biomass indices were generated by applying the U.S. survey length-weight regression relationship ($\text{Weight (kg)} = 0.0000079099 * \text{Length (cm)}^{3.1378}$) to the stratified mean numbers at length from the Canadian survey. Indices of abundance and biomass for the Canadian survey are summarized as stratified mean number/tow from 1986 to 1998 (Table 9C, Figure 4).

Winter flounder captured during the Canadian survey are counted and measured, but not aged. U.S. survey and commercial age keys were used to partition stratified mean numbers at length into stratified mean numbers at age. Sufficient age determinations were available from U.S. NEFSC Spring survey data to partition stratified mean numbers at length into numbers at age for fish smaller than 40 cm. U.S. commercial age keys from the first quarter of the corresponding year were applied for fish longer than 40 cm. The application of commercial age keys will provide unbiased estimates of catch at age if both the U.S. commercial fleet and the Canadian survey are sampling fish that grow at the same rate. Since the principal winter flounder habitat is located in U.S. waters and the Canadian survey samples across both U.S. and Canadian waters with primary catches occurring in U.S. waters, this assumption appears to be valid.

MORTALITY AND MATURATION

Natural Mortality

For this assessment, natural mortality was assumed to be constant and equal to 0.20 throughout the time series. The observation of maximum ages in the populations occasionally exceeding 15 years is consistent with this assumption of natural mortality.

Total Mortality

Estimates of instantaneous total mortality (Z) and fishing mortality (F, assuming natural mortality = 0.20) were estimated from the stratified number at age indices from the U.S. NEFSC Spring and Autumn surveys. Because of interannual variability in the survey indices, pooled estimates of mortality rates were estimated across running three year time periods from 1981 to 1997. Total mortality (Z) was estimated as the natural log of the ratio of ages 3+/4+ indices from the Autumn survey, and ages 4+/5+ indices from the spring survey. Mortality rates for both surveys exhibited similar patterns with relatively low mortality rates in the early 1980s, higher mortality rates in the mid-1980s to early 1990s, and lower mortality rates in the mid-1990s (Figure 6). The two surveys exhibit divergent trends in the most recent years (1993 to 1997), with the spring survey estimate high and increasing fishing mortality, while the Autumn survey estimates lower and decreasing fishing mortality (Figure 6).

Maturity

Maturation determinations for female winter flounder were collected on the NEFSC Spring research vessel survey from 1982 to 1997. The total number of maturation determinations annually is limited, particularly in terms of the number of determinations for ages 2 and 3 fish which determine the character of the maturation relationship at age. We used a logistic regression approach (O'Brien *et al* 1993) to estimate the proportion of females mature at age. Logistic equations for individual years were used to estimate age at 50% maturity for individual years. Age at 50% maturation for female winter flounder appeared to fluctuate without trend from 1982 to 1998 (Table 10). After attempts to pool across various time periods produced stable results, a logistic regression using the entire time series (1982 to 1998) was performed. Age at 50% maturity was estimated to be 1.83 years and the resulting maturity ogive (0.00 at age 1, 0.62 at age 2, 0.92 at age 3, 1.00 at age 4) was used in subsequent analyses (Table 10). O'Brien *et al* (1993) reported age at 50% maturation of 1.9 years and a similar estimated maturity ogive (0.03 at age 1, 0.62 at age 2, 0.99 at age 3, 1.00 at age 4) for data from 1985 to 1989.

ESTIMATES OF STOCK SIZE AND FISHING MORTALITY

Virtual Population Analysis Calibration

The ADAPT virtual population analysis (VPA) calibration method (Parrick 1986, Gavaris 1988, Conser and Powers 1990) was used to estimate terminal stock abundance at ages 2-6 and derive age specific estimates of fishing mortality in 1997 and stock sizes at the beginning of 1998. The catch at age in the VPA consisted of combined U.S. and Canadian landings during 1982 to 1997 for ages 1-6 with a 7+ age group. Indices available to calibrate the VPA included the U.S. NEFSC Spring research vessel survey catch (numbers) at age (ages 1 to 7), the Canadian Spring research vessel Survey catch (numbers) at age (ages 1 to 7), and the U.S. NEFSC Autumn research vessel survey catch (numbers) at age (ages 0 to 6) lagged forward one age and one year. Several VPA calibrations were completed and evaluated during the Southern Demersal Subcommittee and SAW/SARC meetings. A summary of these calibrations including key diagnostics and terminal year results are reported in Table 11.

The final accepted calibration (Run 15) estimated ages 2 to 6 and included the U.S. NEFSC Spring indices (ages 1 to 7), the Canadian Spring indices (ages 1 to 7), and the U.S. NEFSC Autumn indices (ages 1-6, lagged forward one age and one year). This calibration was successful in reducing the coefficients of variation on the youngest ages (2 and 3) and produced favorable diagnostics (Table 11, Appendix 1).

Virtual Population Analysis Results

The assessment results indicate that stock numbers exceeded 25 million in the early 1980s, gradually declined to reach a low level of approximately 8.8 million in 1993, increased to 13.6 million in 1995, and have again declined to 9.6 million fish in 1997 (Table 12). Age 2 recruitment was relatively stable throughout the time period, but larger 1980, 1985, 1987 and 1994 year classes exceed 5 million fish at age 2 (Table 12, Figure 7). Recent recruitment, as measured by the 1995 and 1996 year classes, has been the lowest in the time series (Figure 7). There appears to be little discernible relationship between stock and recruitment over the time period analyzed in this assessment (Figure 7).

Spawning stock biomass declined from levels exceeding 8,000 mt in the early 1980's to less than 2,000 mt in 1994, but increased to almost 3,700 mt in 1996 (Table 12, Figure 7). Spawning stock biomass declined slightly from almost 3,700 mt in 1996 to 3,500 mt in 1997. In the early 1980s, spawning stock biomass consisted of a wide range of ages and the youngest mature ages (2 and 3) comprised less than 40% of the total spawning stock biomass (Figure 8). The age structure of the spawning stock biomass became truncated in the mid 1980s to mid 1990s, when the youngest mature ages (2 and 3) comprised 45% to 75% of the spawning stock biomass. Some broadening of the age structure of spawning stock biomass is evident after 1994, but the age structure spawning component of the stock remains truncated relative to historical levels (Figure 8).

From the early 1980s to the early 1990s, fishing mortality rates ranged from approximately 0.5 to as high as 1.4. Fishing mortality rates declined sharply after 1993 and have fluctuated between 0.3 and 0.5 from 1994 to 1997 (Table 12). There is a reasonable level of agreement between VPA estimated fishing mortality rates and survey estimated rates of fishing mortality (Z) estimates assuming $m=0.2$) throughout the time series (Figure 6). However, in the most recent three years, VPA estimates of fishing mortality correspond more closely with fishing mortality estimates from the Autumn survey. Patterns in fishing mortality appear to be reasonably well correlated with reported landings included in the assessment (Figure 9).

Precision Estimates of F and SSB

Uncertainty and potential bias estimates were assessed using a bootstrap analysis of the VPA calibration. One thousand bootstrap realizations were produced by randomly resampling survey residuals produced by the final ADAPT calibration. Bootstrap abundance indices had slightly larger CV's than the least squares estimates produced by the final ADAPT VPA calibration (Appendix 2). Estimates of bias on all ages were relatively low, ranging from 3.7% to 6.4%. Bias estimates for fully recruited F and spawning stock biomass were each below 3%.

The distribution of bootstrap realizations of spawning stock biomass indicates that there is an 80% chance that the 1997 estimate of SSB is between 3,100 and 4,200 mt (Figure 10). The distribution of bootstrap realizations of fishing mortality suggests that there is an 80% probability that F_{1997} is between 0.33 and 0.51 (Figure 10).

Retrospective Analysis

Retrospective analyses of the Georges Bank winter flounder VPA were performed from 1997 to 1990 by sequentially reanalyzing the ADAPT calibration after removing the terminal year of input data. Retrospective patterns for fishing mortality (Figure 11A) indicate a pattern of slightly overestimating average fishing mortality in the terminal year. The tendency was more pronounced in the terminal year 1992 and 1993 assessments. The retrospective patterns for spawning stock biomass (Figure 11B) indicate that there is a tendency in the most recent years to slightly overestimate spawning stock biomass in the terminal year. This pattern shifts before 1993 with a tendency to underestimate SSB in the terminal year estimates evident before 1993.

The retrospective patterns for age 2 recruitment (Figure 11C) indicate considerable variability in the performance of the terminal year estimation of stock numbers at age 2. Performance was

generally acceptable with a slight tendency to underestimate age 2 recruitment for most year classes. However, retrospective performance was particularly poor for the 1992 and 1994 year classes, where initial estimates were considerably higher than converged estimates of these year classes. Both of these year classes had estimated age 1 landings included in the catch at age, whereas landings at age from other year classes indicated no landings at age 1. This observation should be considered when evaluating the reliability of the terminal estimate of age 2 recruitment, which estimates that incoming age 2 recruitment is the weakest in the time series.

BIOLOGICAL REFERENCE POINTS

Yield and Spawning Stock Biomass per Recruit Analyses

Yield per recruit (Thompson and Bell 1934) and yield per recruit (Gabriel *et al.* 1989) analyses were conducted using the partial recruitment vector estimated from the calibrated VPA. Since major fishery management measures have been implemented beginning in 1994, 4-year (1994-1997) arithmetic mean weights and geometric mean partial recruitment were used as inputs in these analyses. The maturation schedule for Georges Bank winter flounder has been stable through time, so the long term estimate of the maturation schedule was used as an input. Results of the analysis indicate that $F_{0.1}$ is currently estimated to be 0.21, F_{\max} is estimated to be 0.42, and $F_{20\%}$ is estimated to be 0.47 (Table 13, Figure 12).

SFA Overfishing Definitions

The Overfishing Definition Review Panel (Applegate *et al.* 1998) proposed an MSY based harvest control rule for Georges Bank winter flounder derived from survey based proxies of biomass and exploitation. The panel defined maximum sustainable yield as 2,700 mt, identified a threshold fishing mortality proxy (F_{MSY}) as a level of an exploitation index (catch/U.S. NEFSC Autumn survey biomass) of 0.98, and identified a target stock biomass proxy as the U.S. NEFSC Autumn survey biomass index value of 2.74. Further, target fishing mortality proxy was estimated to be 75% of the threshold proxy value, and stock biomass proxies were established as 50% of the target B_{MSY} proxy values. Figure 13 provides a graphic representation of the SFA overfishing definition.

A non-equilibrium surplus production analysis (ASPIC, Prager 1993, 1994) was completed using landings biomass and the U.S. NEFSC Spring, Canada spring, and U.S. NEFSC Autumn survey indices of stock biomass from 1963 to 1997 to provide perspective on historical stock levels and to provide information relative to SFA reference points (Appendix 3). Initial biomass, maximum sustainable yield, the intrinsic rate of increase and catchability (q) of the survey biomass indices were estimated by nonlinear least squares of the biomass index residuals.

The current surplus production model differed from the model used to construct the SFA harvest control rule in two respects. First, the catch input included foreign landings (primarily from the 1960s) that were not included in the surplus production model. Second, the strata set used to estimate the U.S. NEFSC Spring and Autumn indices included a larger strata set than the indices used to estimate the SFA harvest control rule. The two strata sets produced highly correlated survey indices, although the current survey indices are scaled lower than the previous indices.

Results of the surplus production analysis indicated a reasonable fit to the input data, and estimated trends in biomass were well matched with results from the Virtual Population Analysis (Figure 14, Appendices 1 and 3). A maximum sustainable biomass (MSY) of 3,100 mt was estimated to be produced by a biomass (B_{msy}) of 11,400 mt (Table 14). A time trajectory of results from the surplus production model indicates that yield has generally exceeded estimated surplus production for the past two decades (Figure 15).

The SFA harvest control rule was re-estimated in its original format based on a current NEFSC research vessel survey indices (revised strata set) and a revised surplus production model that incorporated the Canadian research vessel survey indices and foreign commercial landings in the 1960s and early 1970s. The target B_{MSY} proxy (U.S. NEFSC Autumn Survey biomass units) was estimated to be 2.730 (MSY/ f_{msy}), and the threshold B_{MSY} proxy was estimated to be 50% of the B_{MSY} proxy. The threshold and target F_{msy} proxies (in exploitation index units) were estimated to be 1.125 (MSY Proxy / B_{msy} proxy) and 0.843 (0.75* $F_{threshold}$ proxy), respectively.

The revised harvest control rule is displayed graphically in Figure 13. For the latest time period for which data were available (1995-1997), the three year average of the U.S. NEFSC Autumn survey index (1.542) and the exploitation index (0.754) indicate that overfishing was occurring and that the stock was in an overfished condition relative to the harvest control rule. If the harvest control rule were applied for the 1999 fishing year, the corresponding threshold fishing mortality rate (fully recruited F) would be 0.04 and the target fishing mortality rate (fully recruited F) would be 0.03.

PROJECTIONS

Short Term Stochastic Projections

Short term deterministic projections were performed for 1998, 1999, and 2000. 1998 U.S. landings were assumed to be 964 mt based on the landings projections by the New England Fishery Management Council's Multispecies Monitoring Committee. Canadian landings in 1998 were assumed to be equal to 1997 landings. The projections were based on a partial recruitment vector estimated as the geometric mean of 1994 to 1997 F's at age from the final VPA calibration, 1994 to 1997 arithmetic mean stock and catch weights, and the long term (1982-1997) maturity schedule for Georges Bank winter flounder. Age 1 recruitment was estimated from the terminal year bootstrap realizations of the VPA in 1998, and recruitment in 1999 and 2000 was resampled from observed age 2 recruitment estimated by the ADAPT VPA calibration from 1982 to 1997 (Age Pro Model 3).

Projections were run at $F = 0.00$ (maximum stock rebuilding rate), $F_{target} = 0.03$ (management target associated with the revised SFA harvest control rule), $F_{threshold} = 0.04$ (management threshold associated with the revised SFA harvest control rule), $F_{0.1} = 0.21$ (commonly used yield per recruit reference point), $F_{1998} = 0.34$ (based on projected landings of 1,107 mt in 1998), and $F_{20\%} = 0.47$ (current New England Fishery Management Council overfishing definition) for years 1999 and 2000. Results for these reference points of F are presented in Table 15.

Projections at $F = 0.00$ in 1999/2000 provide a benchmark for the maximum projected stock rebuilding rate. For this level of fishing mortality (i.e., fishery closure), there would be no

projected landings. Age 1+ biomass is projected to increase 33% from 5,680 mt in 1999 to 7,552 mt in 2000. Spawning stock biomass is projected to increase from 44% from 3,735 mt in 1999 to 5,374 mt in 2000 (Table 15, Figure 16). Accounting for some sources of uncertainty in the stock assessment, there is an 80% chance that SSB in 2000 would be between 4,098 mt and 6,793 mt (Table 15).

Projections at $F_{target} = 0.03$ in 1999/2000 result in a 91% decline in landings from 1,107 mt in 1998 to 118 mt in 1999 (Table 15, Figure 16). Age 1+ biomass is projected to increase 31% from 5,619 mt in 1999 to 7,342 mt in 2000. Spawning stock biomass is projected to increase 41% from 3,716 mt in 1999 to 5,228 mt in 2000. Accounting for some sources of uncertainty in the stock assessment, there is an 80% chance that SSB in 2000 would be between 3,986 mt and 6,613 mt (Table 15).

Projections at $F_{threshold} = 0.04$ in 1999/2000 result in an 86% decline in landings from 1,107 mt in 1998 to 157 mt in 1999 (Table 15, Figure 16). Age 1+ biomass is projected to increase 30% from 5,600 mt in 1999 to 7,274 mt in 2000. Spawning stock biomass is projected to increase 40% from 3,709 mt in 1999 to 5,181 mt in 2000. Accounting for some sources of uncertainty in the stock assessment, there is an 80% chance that SSB in 2000 would be between 3,948 mt and 6,552 mt (Table 15).

Projections at $F_{0.1} = 0.21$ in 1999/2000 result in a 31% decline in landings from 1,107 mt in 1998 to 764 mt in 1999 (Table 15, Figure 16). Age 1+ biomass is projected to increase 18% from 5,279 mt in 1999 to 6,244 mt in 2000. Spawning stock biomass is projected to increase 24% from 3,597 mt in 1999 to 4,446 mt in 2000. Accounting for some sources of uncertainty in the stock assessment, there is an 80% chance that SSB in 2000 would be between 3,377 mt and 5,639 mt (Table 15).

Based on projected landings of 1,107 mt in 1998, the projected level of fishing mortality in 1998 is 0.34. Fishing at $F_{1998} = 0.34$ in 1999/2000, landings would increase by 6% from 1,107 mt in 1998 to 1,172 mt in 1999 (Table 15, Figure 16). Age 1+ biomass is projected to increase 11% from 5,050 mt in 1999 to 5,596 mt in 2000. Spawning stock biomass would increase 13% from 3,514 mt in 1999 to 3,967 mt in 2000. Accounting for some sources of uncertainty in the stock assessment, there is an 80% chance that SSB in 2000 would be between 3,004 mt and 5,046 mt (Table 15).

The overfishing definition previously established by the New England Fishery Management Council for Georges Bank winter flounder is $F_{20\%}$, which is currently estimated to be 0.47. Fishing at $F_{20\%} = 0.47$ in 1999/2000, landings would increase by 42% from 1,107 mt in 1998 to 1,575 mt in 1999 (Table 15, Figure 16). Age 1+ biomass is projected to increase 4% from 4,836 mt in 1999 to 5,042 mt in 2000. Spawning stock biomass is projected to increase 3% from 3,433 mt in 1999 to 3,550 mt in 2000. Accounting for some sources of uncertainty in the stock assessment, there is an 80% chance that SSB in 2000 would be between 2,676 mt and 4,529 mt.

CONCLUSIONS

The Georges Bank winter flounder stock is overexploited and at a low level of biomass. Fishing mortality rates were very high in the early 1990s (1990-1993 average $F=0.74$), but have declined since 1994. Spawning stock biomass levels and age composition have improved since 1993, but incoming recruitment, particularly the 1995 and 1996 year classes, is poor. Stock biomass in 1997 was at 60% of the biomass proxy specified in the SFA harvest control rule. Assuming a catch of 1,100 mt in 1998, the estimated level of SSB in 1998 is 3,300 mt and fully recruited F is projected to increase to 0.34. Relative to the SFA overfishing definition and control rule, the stock was in an overfished condition and overfishing was occurring.

ACKNOWLEDGMENTS

The Resource Survey Branch and Fishery Biology Investigation were instrumental in providing long term research vessel survey data and age determinations for commercial and survey samples. Susan Wigley and Ralph Mayo have continued to generate methodology and preliminary estimates of prorated winter flounder landings to stock areas. Dr. Mark Terceiro, Gary Shepherd, and Paul Nitschke fine tuned the proration methodology to account for specific patterns occurring with respect to winter flounder. Stratis Gavaris provided data on the Department of Fisheries and Oceans, Canada research vessel survey of Georges Bank. Dr. Ray Conser was responsible for the development of the algorithms used in the ADAPT and bootstrapping procedures and Dr. Laura Shulman developed the FORTRAN implementation and Visual Basic interface for these algorithms in a user-friendly environment. A draft of this report was presented to the Southern Demersal Working Group of the SAW (October 13-16, 1998, Woods Hole) chaired by Dr. Terceiro. Ralph Mayo and Dr. Terry Smith provided significant editorial comments that improved the quality of this document.

Table 8. Standardized, stratified abundance (numbers) and biomass (weight) indices for Georges Bank winter flounder from the U.S. NEFSC Spring and Autumn, and Canadian Spring research vessel bottom trawl surveys (U.S. survey strata 01130-01220; Canadian survey strata 5Z1-5Z8). Canadian biomass indices were estimated using the stratified mean number at length and the U.S. survey length-weight regression coefficients. Door standardization coefficients of 1.46 (numbers) and 1.39 (weight) were applied to U.S. survey indices before 1985 to account for differences in catchability between survey doors (Forrester et al. 1997).

Table 9C. Stratified mean catch/tow (numbers) of Georges Bank winter flounder (DFO strata 5Z1-5Z8) in the Canadian Spring research vessel bottom trawl survey. Age keys were used from the corresponding U.S. NEFSC Spring survey for fish less than 40 cm, and from U.S. commercial age keys for fish greater than or equal to 40 cm. Commercial ages were unavailable for 1998 so only U.S. survey ages were used to partition the 1998 stratified mean length indices.

Table 15. Results of short-term stochastic projections of landings (mt) in the 1999 and spawning stock biomass (mt) in 2000 for Georges Bank winter flounder. Landings in 1998 were assumed to be 1,107 mt based on projections by the NEFMC Multispecies Monitoring Committee and assumed Canadian landings, resulting in a realized F of 0.34 in 1998. Projected landings and spawning stock biomass estimates are provided for the 10th, 50th, and 90th percentiles for various levels of fishing mortality in 1999 including current and proposed biological reference points.

Fishing Mortality	Landings (mt) in 1999			Total Stock Biomass (mt) in 2000			Spawning Stock Biomass (mt) in 2000		
	10%	50%	90%	10%	50%	90%	10%	50%	90%
0.00	0	0	0	5,863	7,552	9,423	4,098	5,374	6,793
0.03 (F_{target})	89	118	150	5,695	7,342	9,170	3,986	5,228	6,613
0.04 ($F_{threshold}$)	119	157	199	5,641	7,274	9,088	3,948	5,181	6,552
0.21 ($F_{0.1}$)	578	764	969	4,804	6,244	7,848	3,377	4,446	5,639
0.34 (F_{1998})	888	1,172	1,487	4,275	5,596	7,068	3,004	3,967	5,046
0.47 (F_{20t})	1,195	1,576	2,011	3,823	5,042	6,406	2,676	3,550	4,529

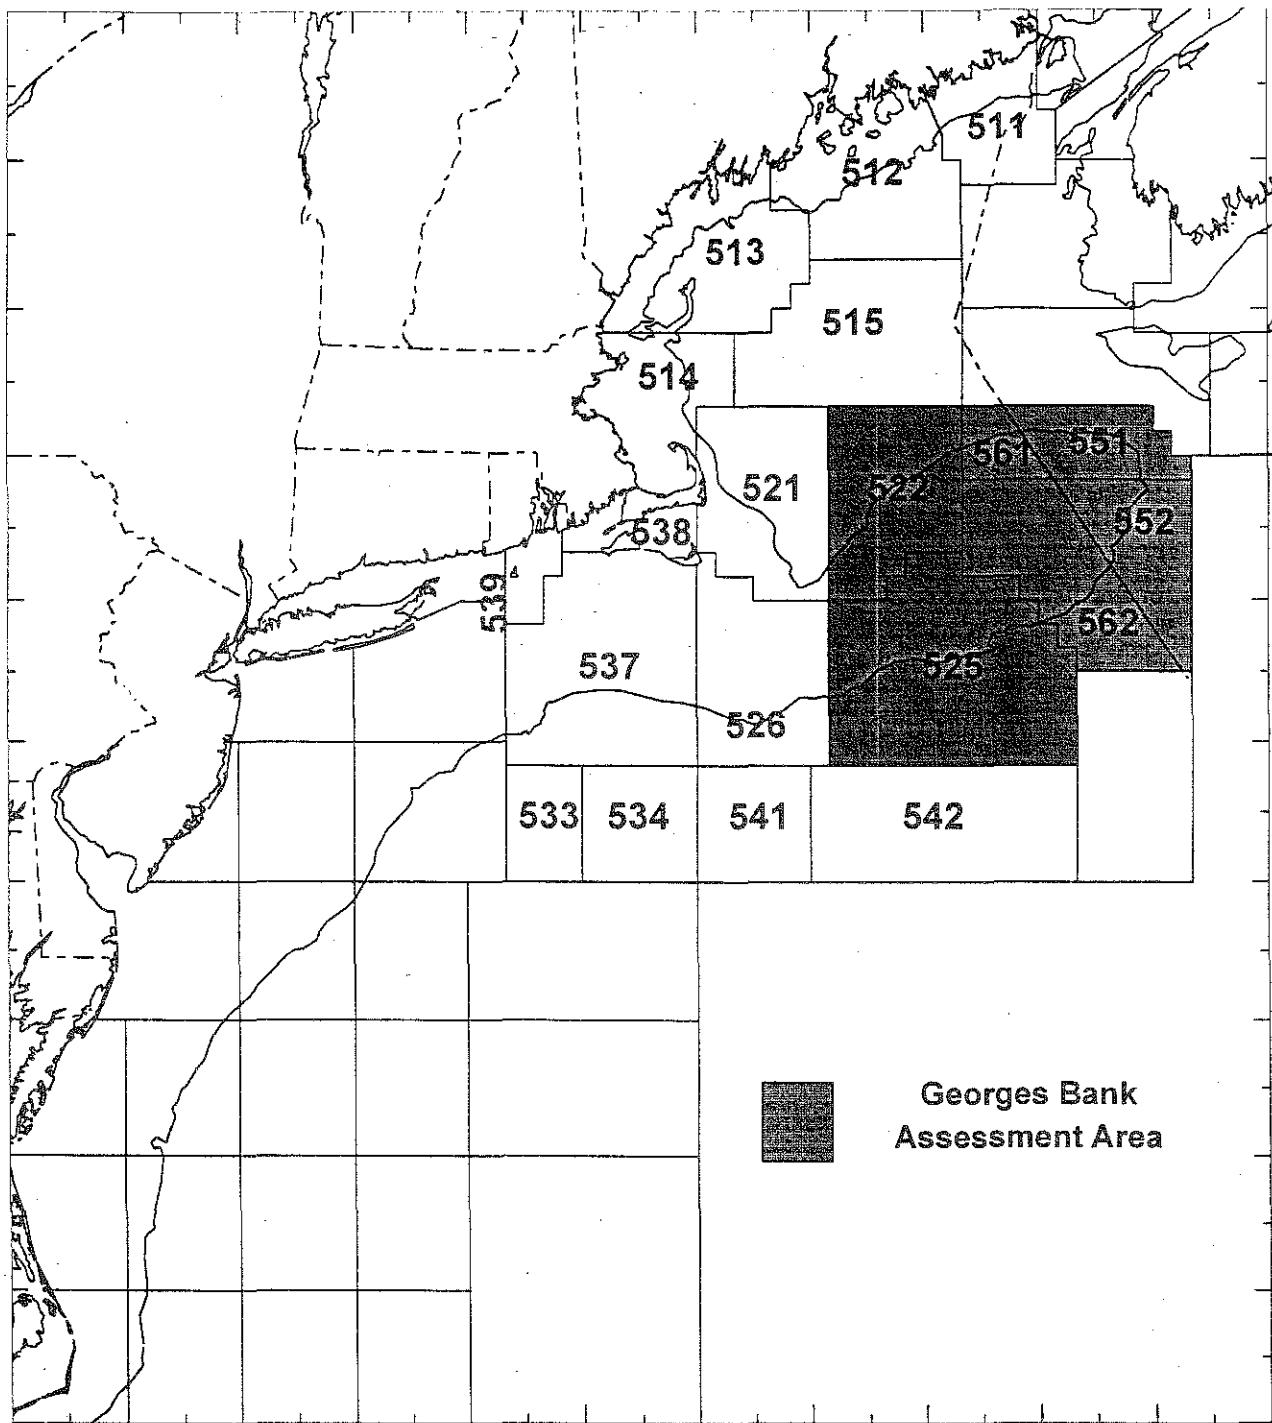

Figure 1. NEFSC statistical areas included in the Georges Bank winter flounder assessment.

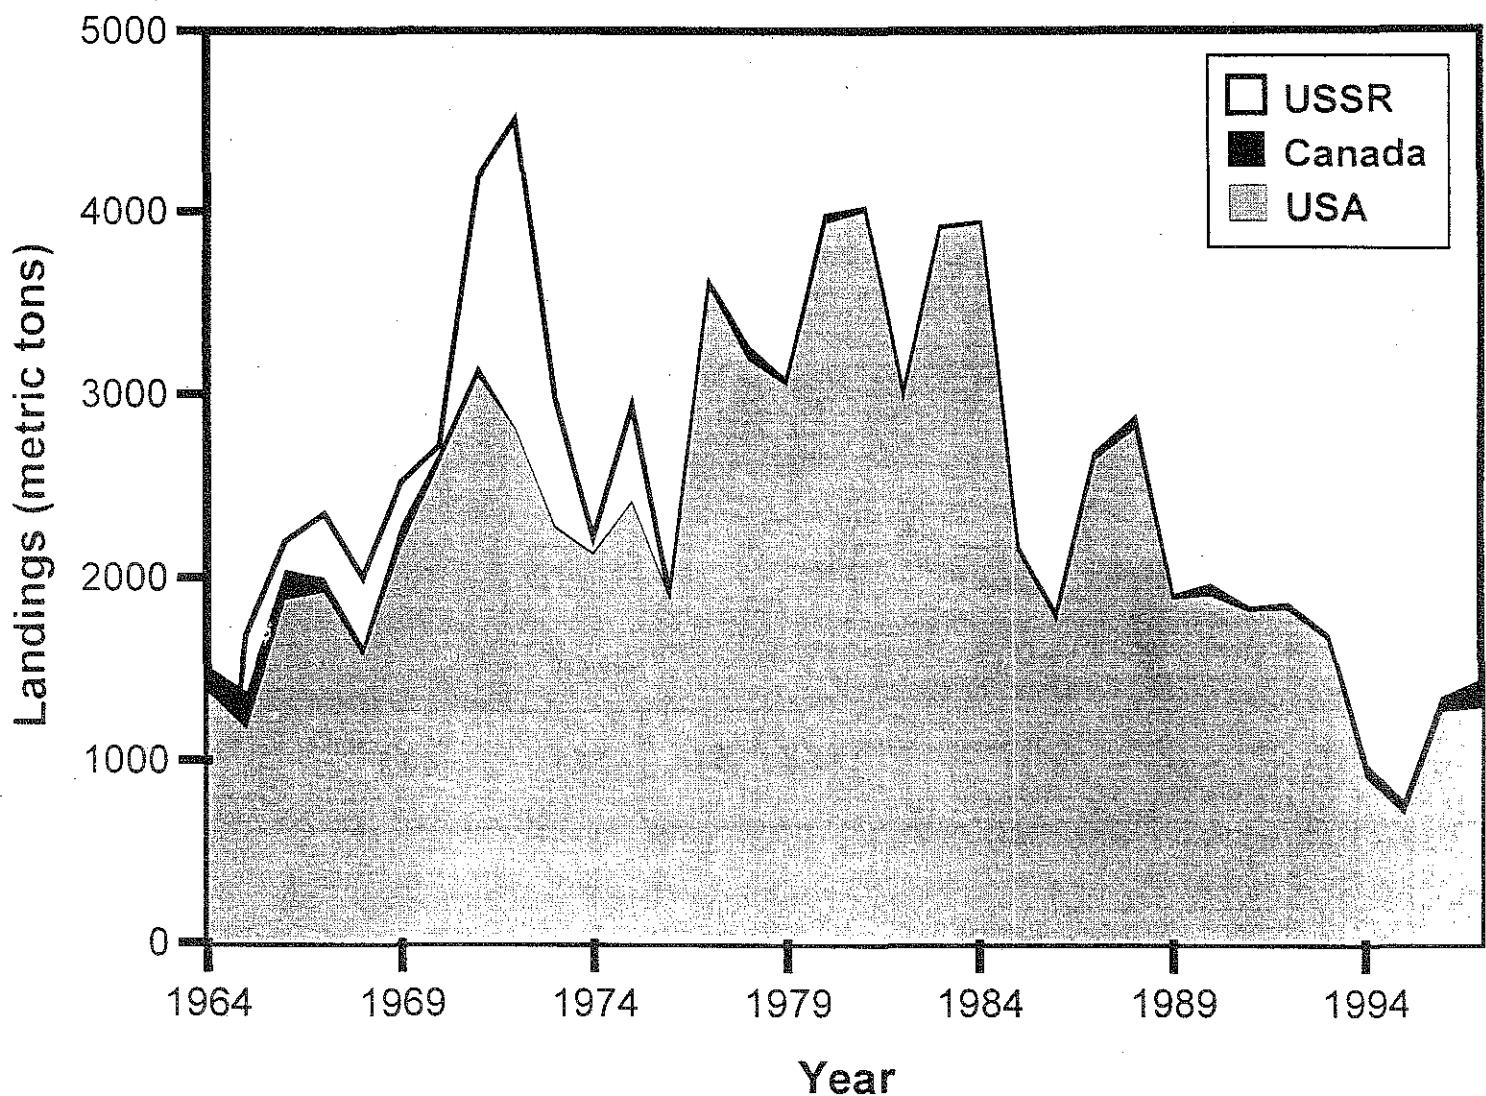

Figure 2. Total commercial landings (mt) of winter flounder from the Georges Bank stock (U.S. statistical areas 522-525, 551-562; NAFO areas 5Zh,j,m,n).

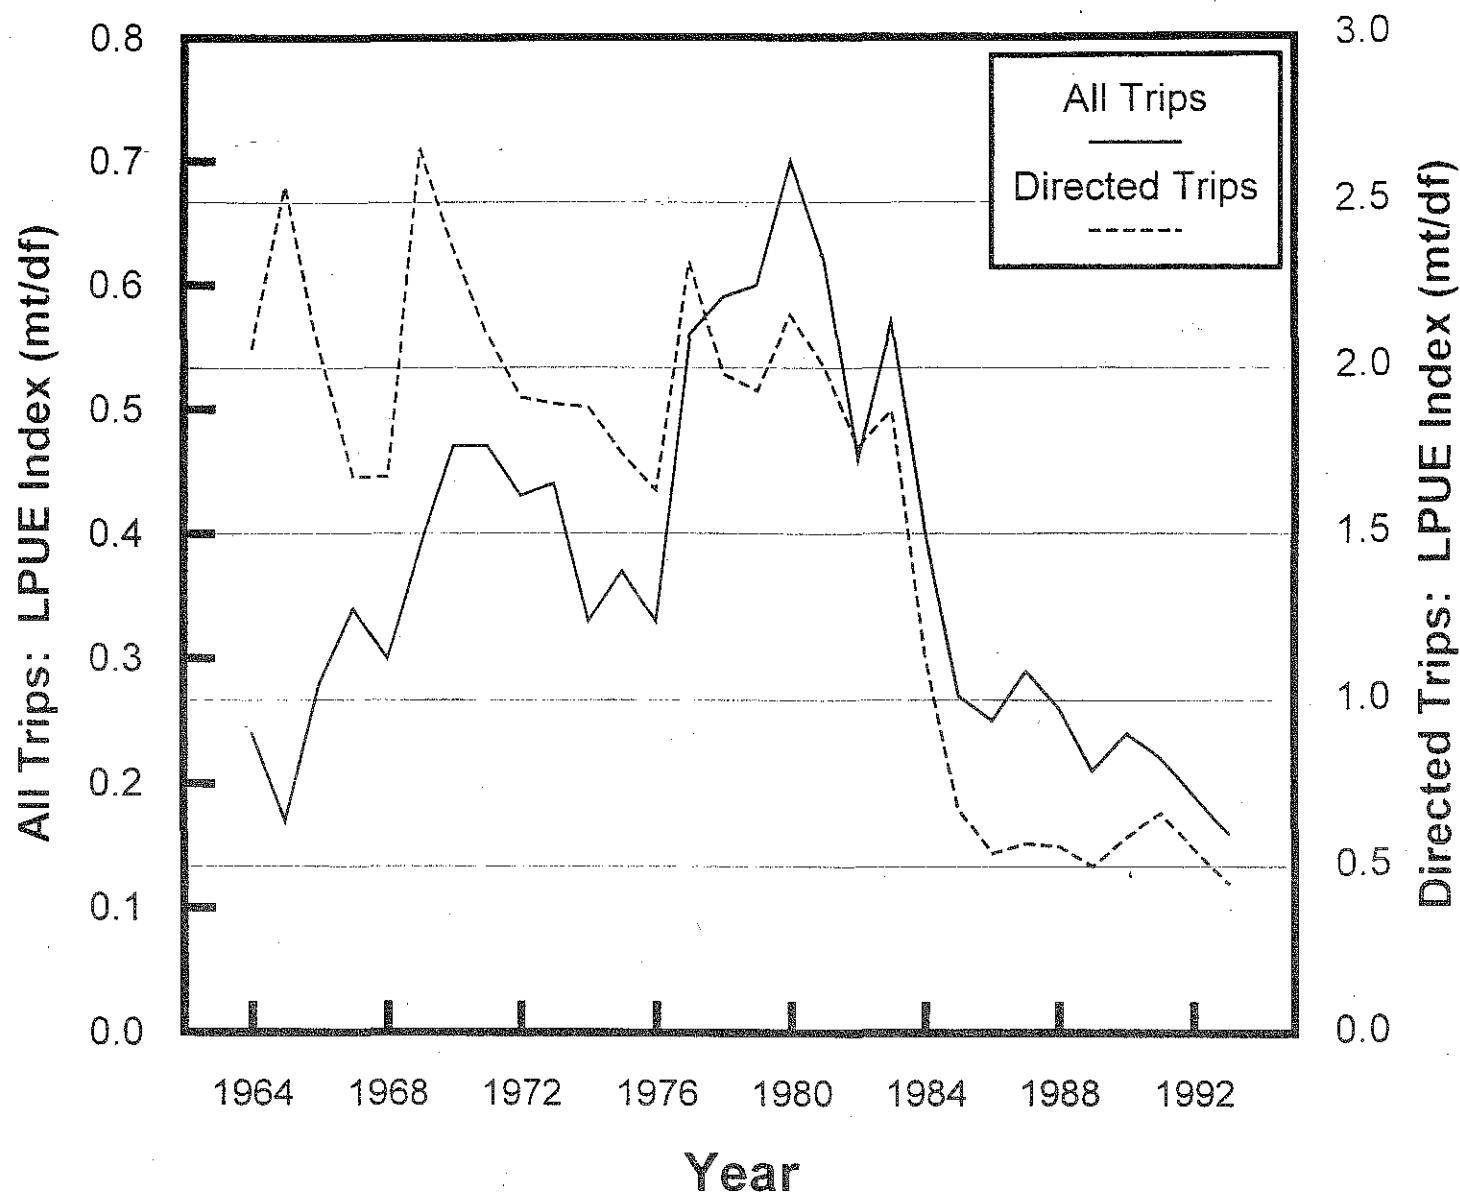

Figure 3. Unstandardized landings (mt) per unit effort (days fished) for all otter trawl trips landing winter flounder and for directed trips (trips where landings of winter flounder constitute 50% or more of the trip).

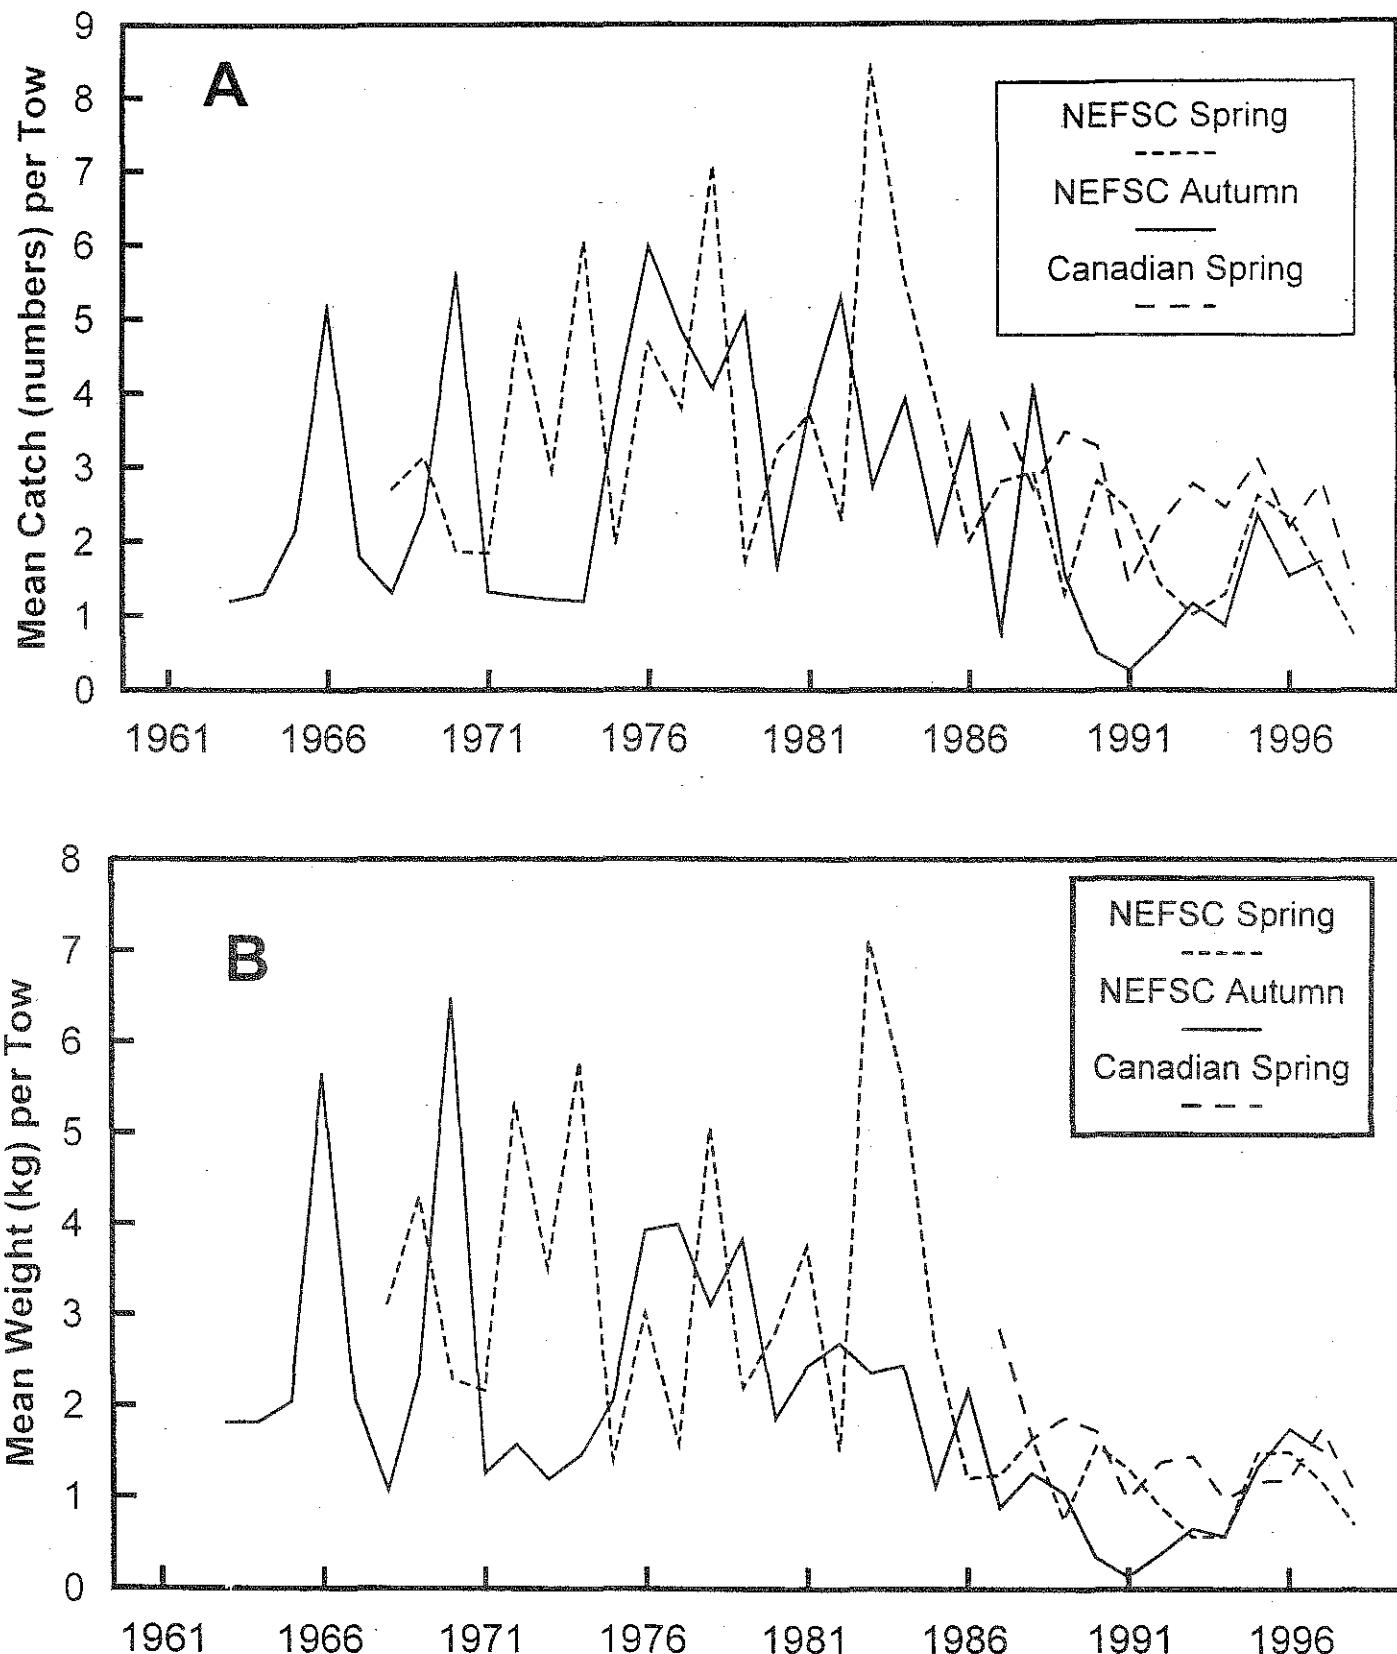

Figure 4. U.S. and Canadian research vessel bottom trawl survey abundance (number per tow; top panel) and biomass (kg per tow; bottom panel) for Georges Bank winter flounder, 1963-1998. Canadian weight per tow was estimated using the stratified mean number per tow at length and the U.S. survey length-weight regression equation.

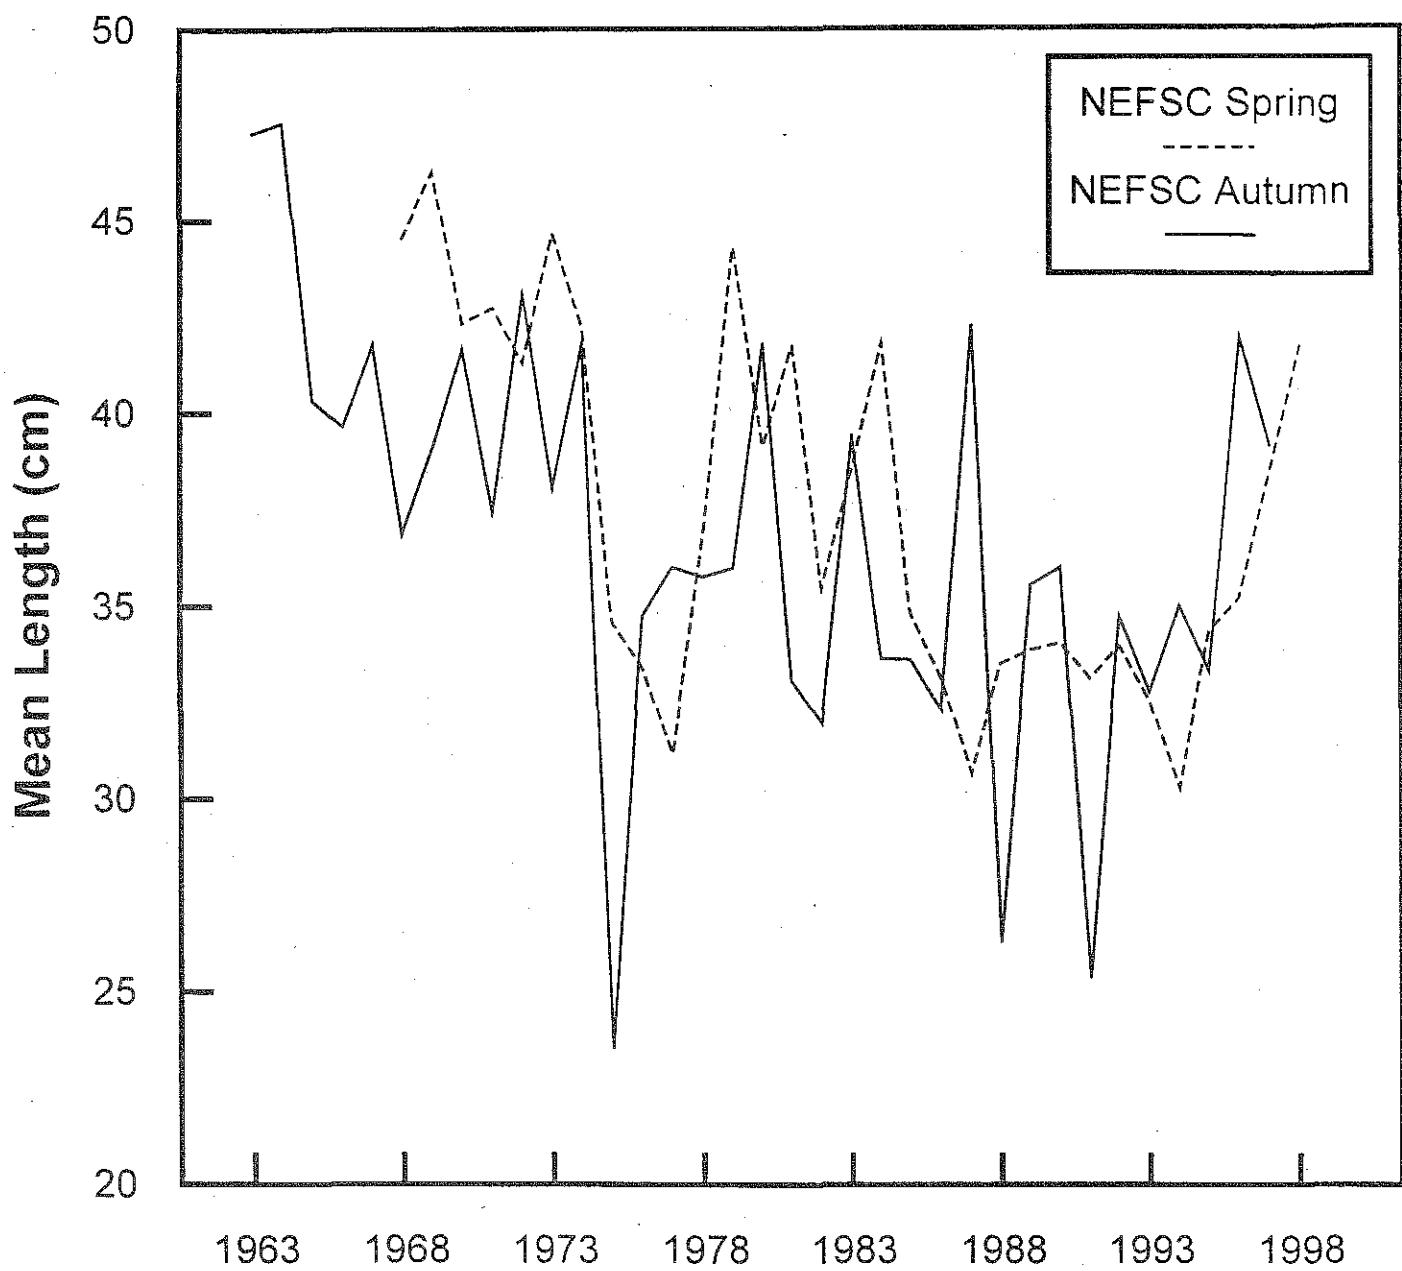

Figure 5. Stratified mean length of Georges Bank (NEFSC offshore strata 13-22) winter flounder from the NEFSC spring and autumn research vessel surveys.

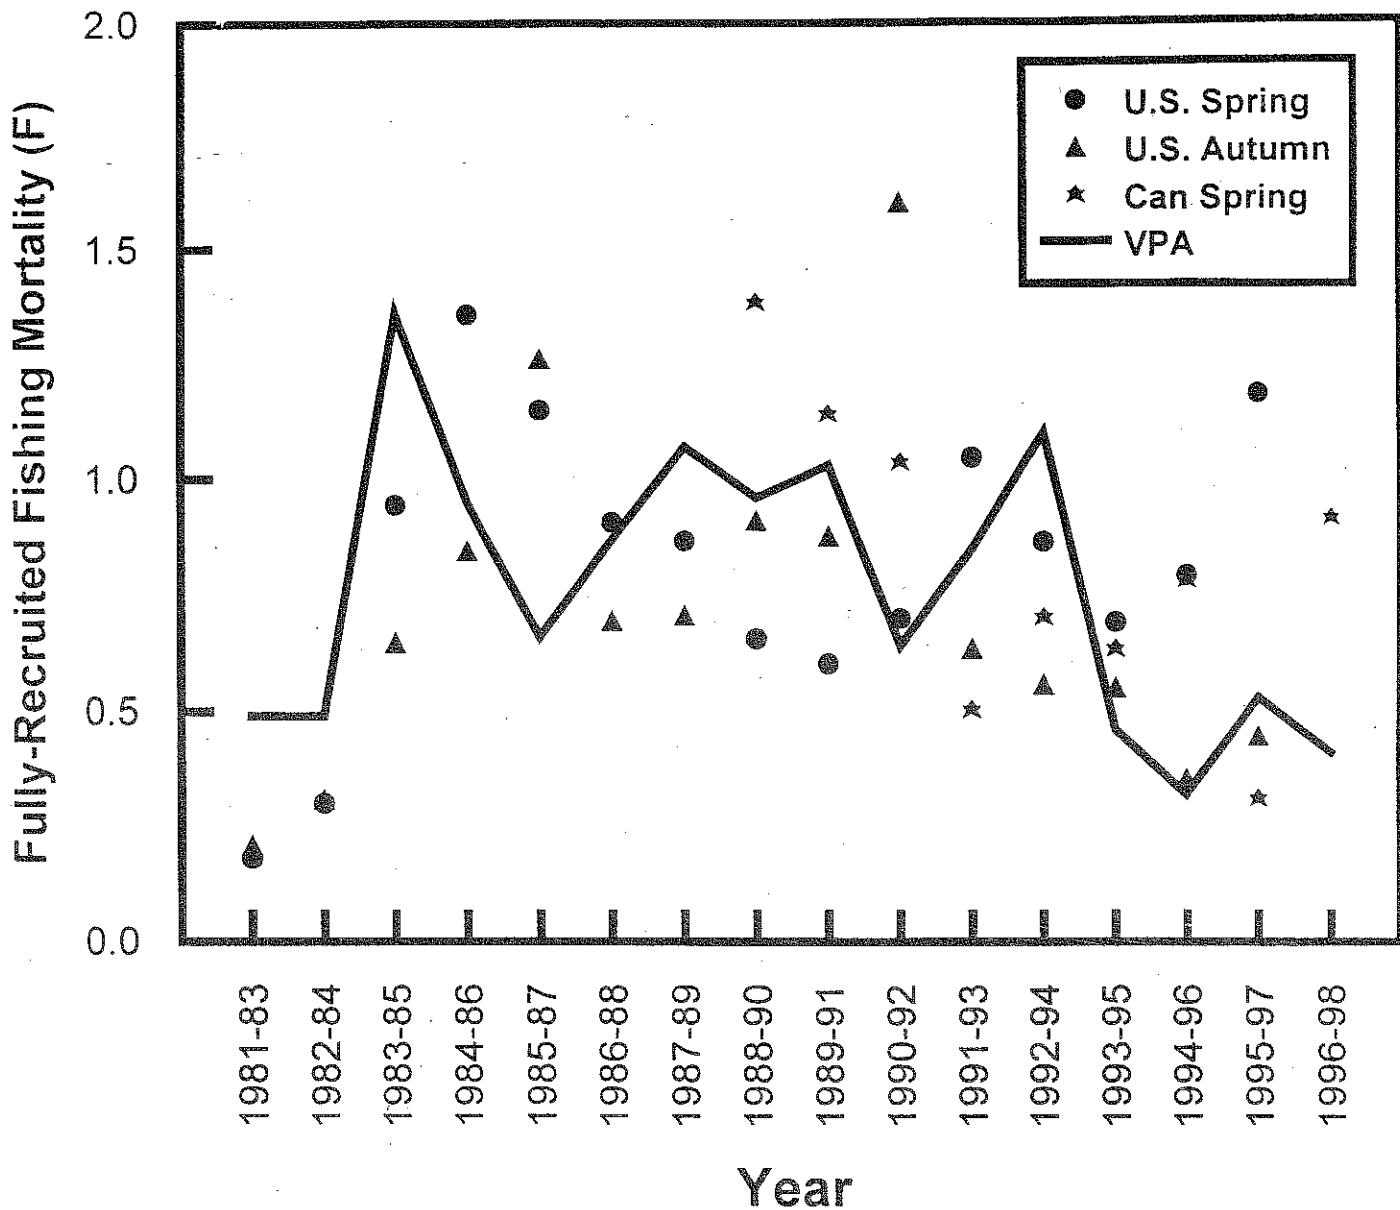

Figure 6. Comparison of estimated instantaneous fishing mortality rate estimated from NEFSC research vessel catch numbers at age with VPA estimates of average unweighted F for ages 4-6. The x-axis labels give the 3-year average used to generate the survey based estimates of F . The midpoint of this range (i.e., 1982 for the range 1981-83) corresponds to the VPA estimates of F .

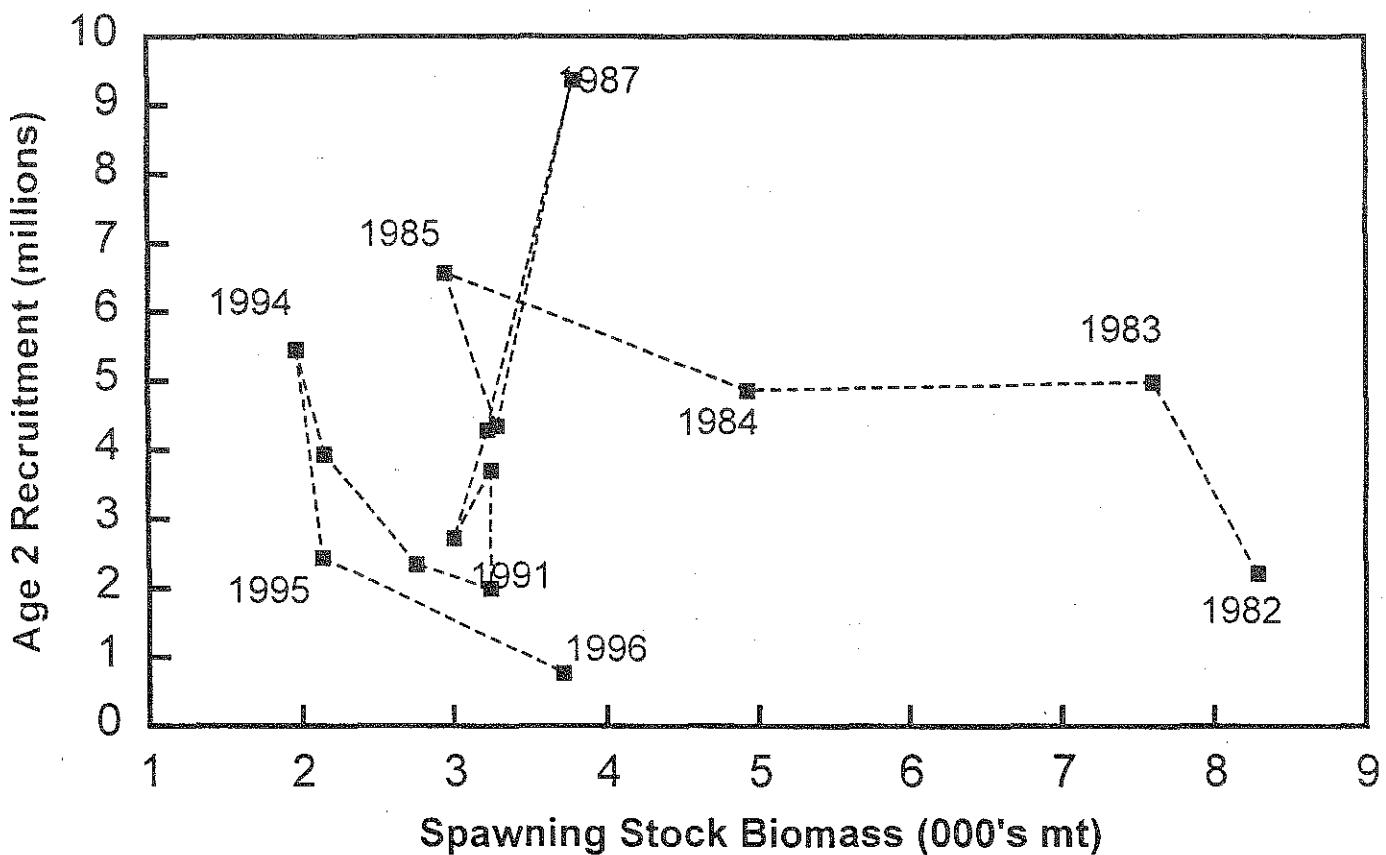

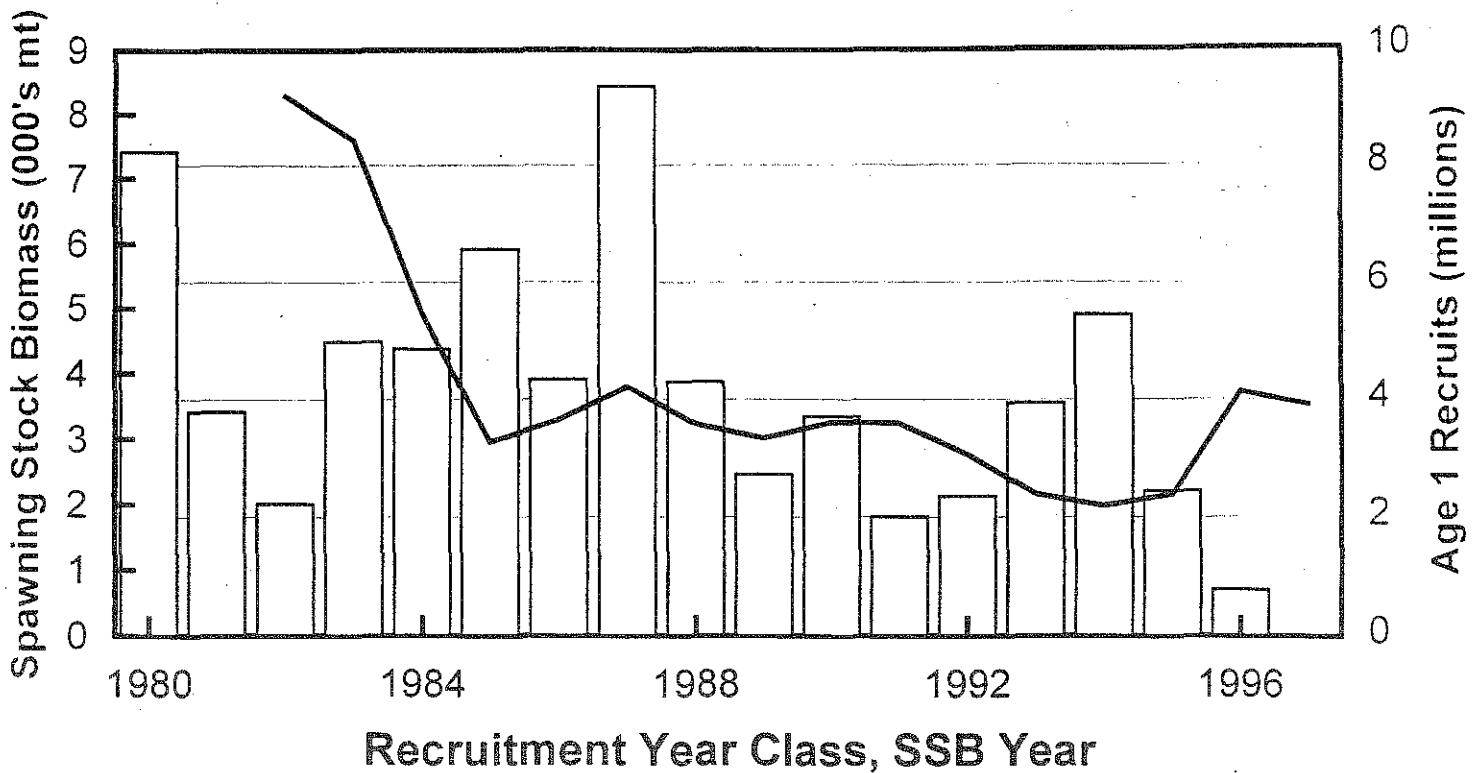

Figure 7. Trends in spawning stock biomass (line) and age 2 recruitment (bars) estimated from Virtual Population Analysis for Georges Bank winter flounder from 1980 to 1997.

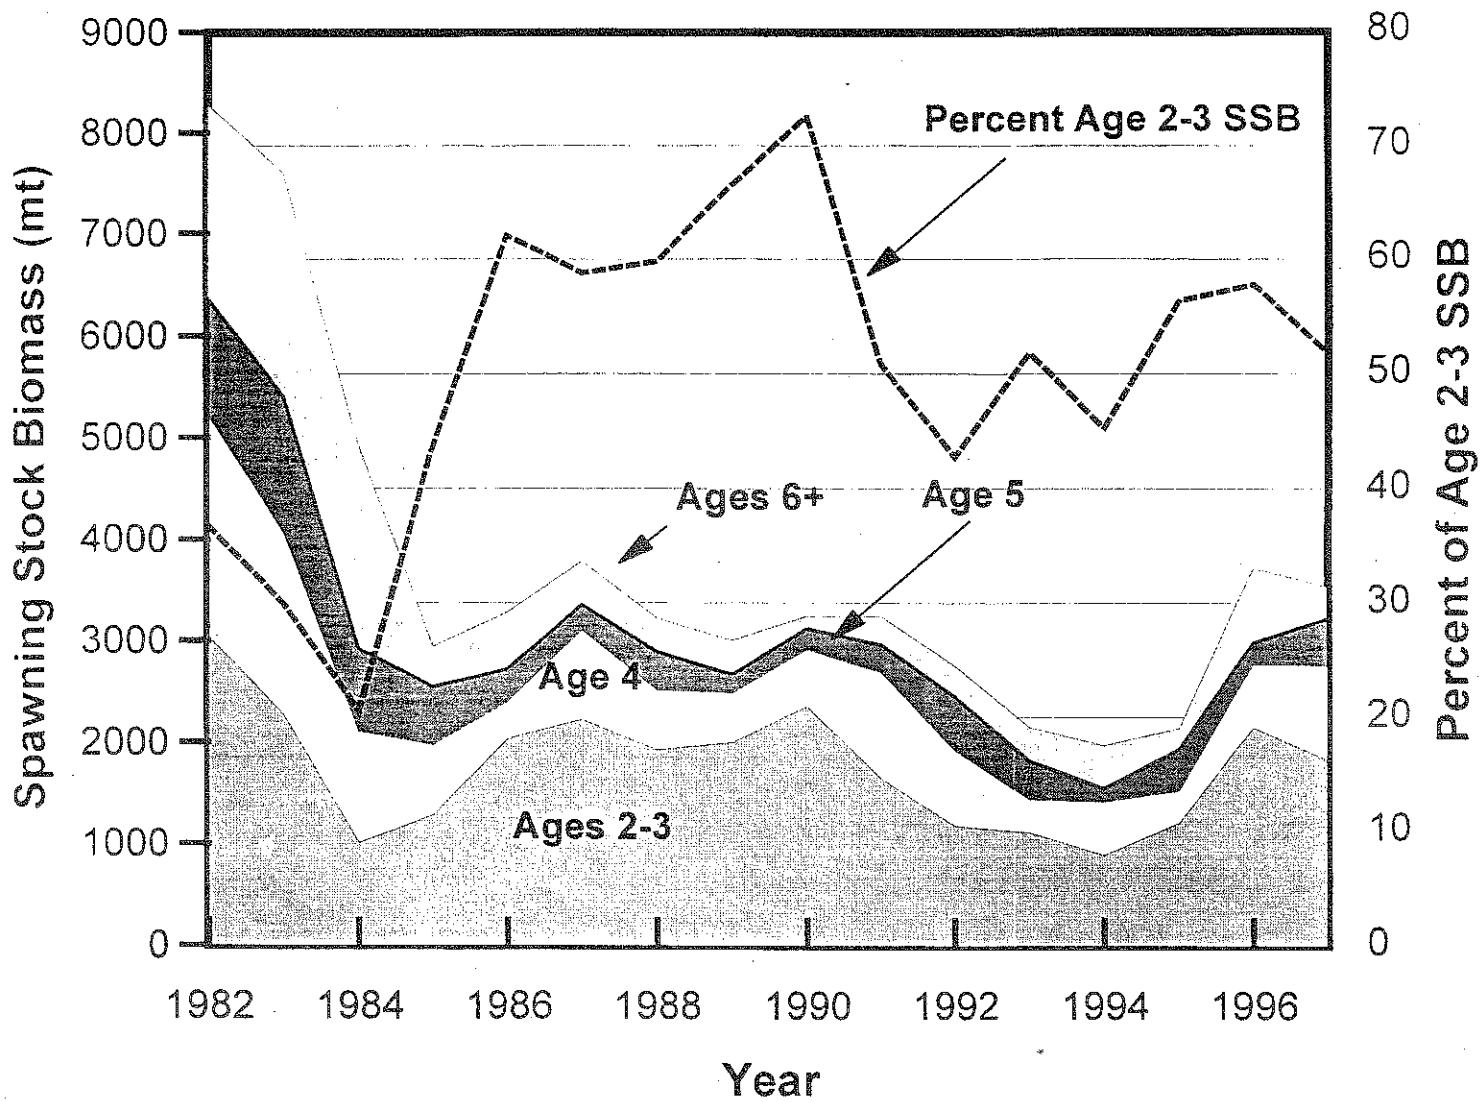

Figure 8. Age composition of the spawning stock biomass estimated from Virtual Population Analysis for Georges Bank winter flounder from 1982 to 1997.

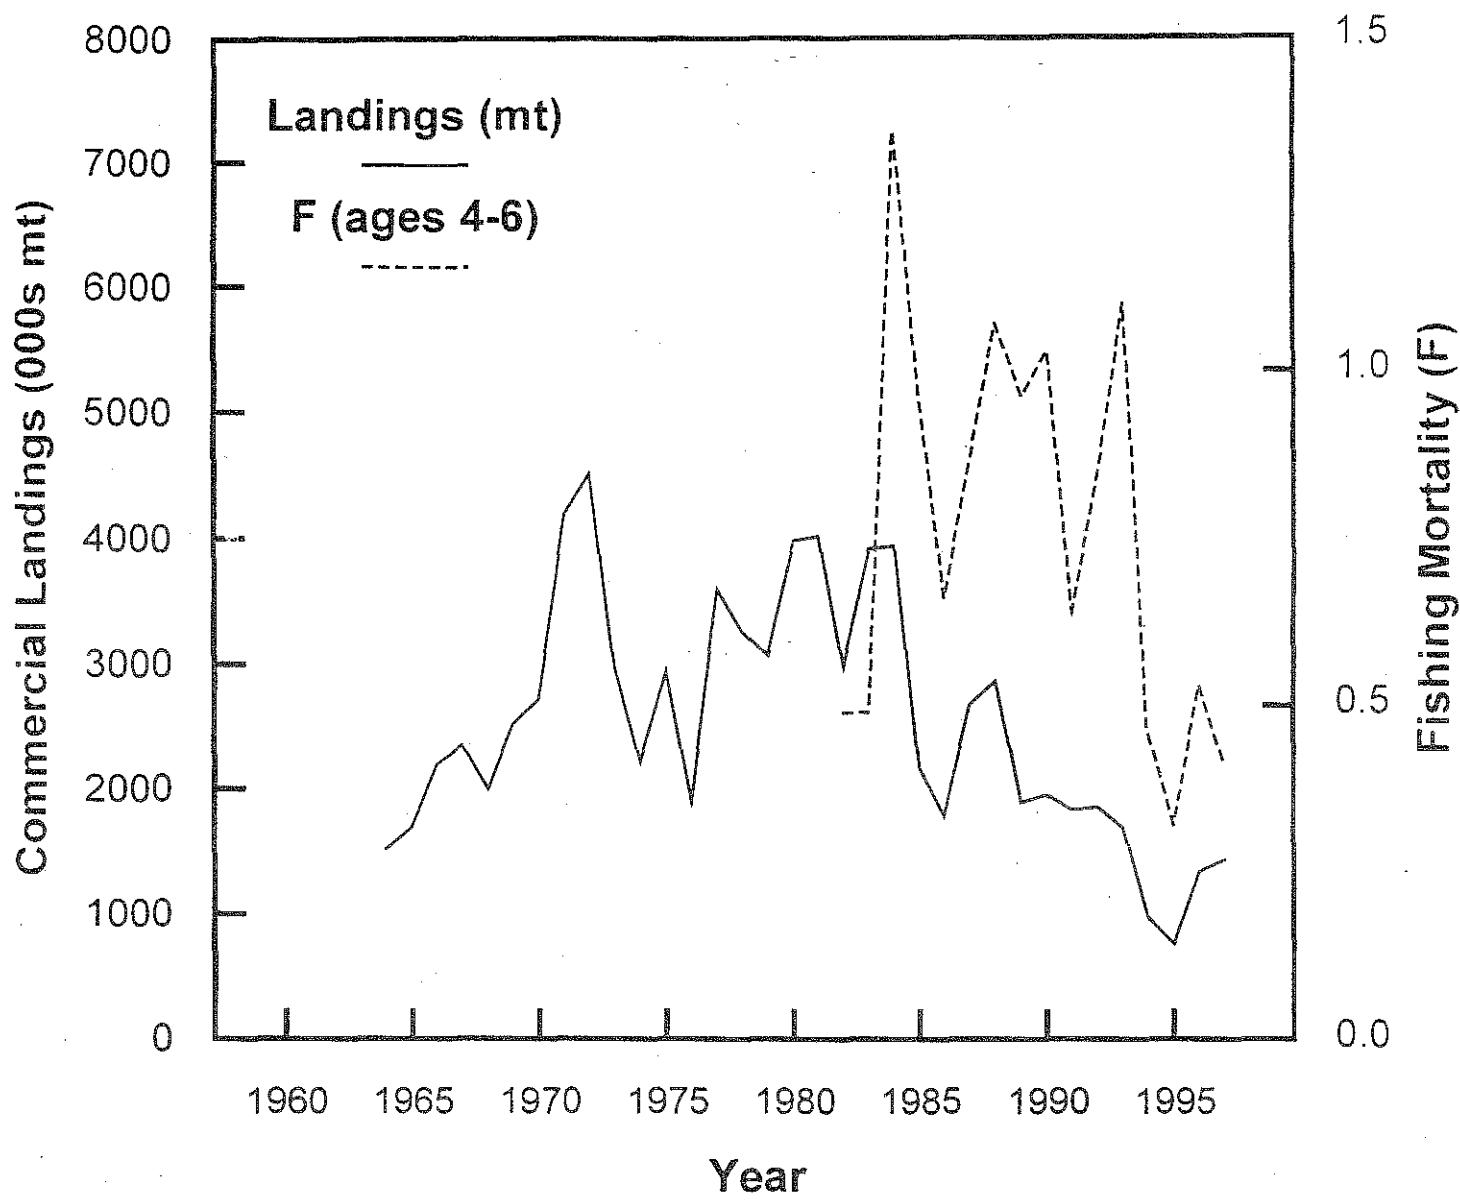

Figure 9. Trends in commercial landings (mt) and fully-recruited fishing mortality (F , ages 4-6, unweighted) estimated from Virtual Population Analysis for Georges Bank winter flounder from 1964 to 1997.

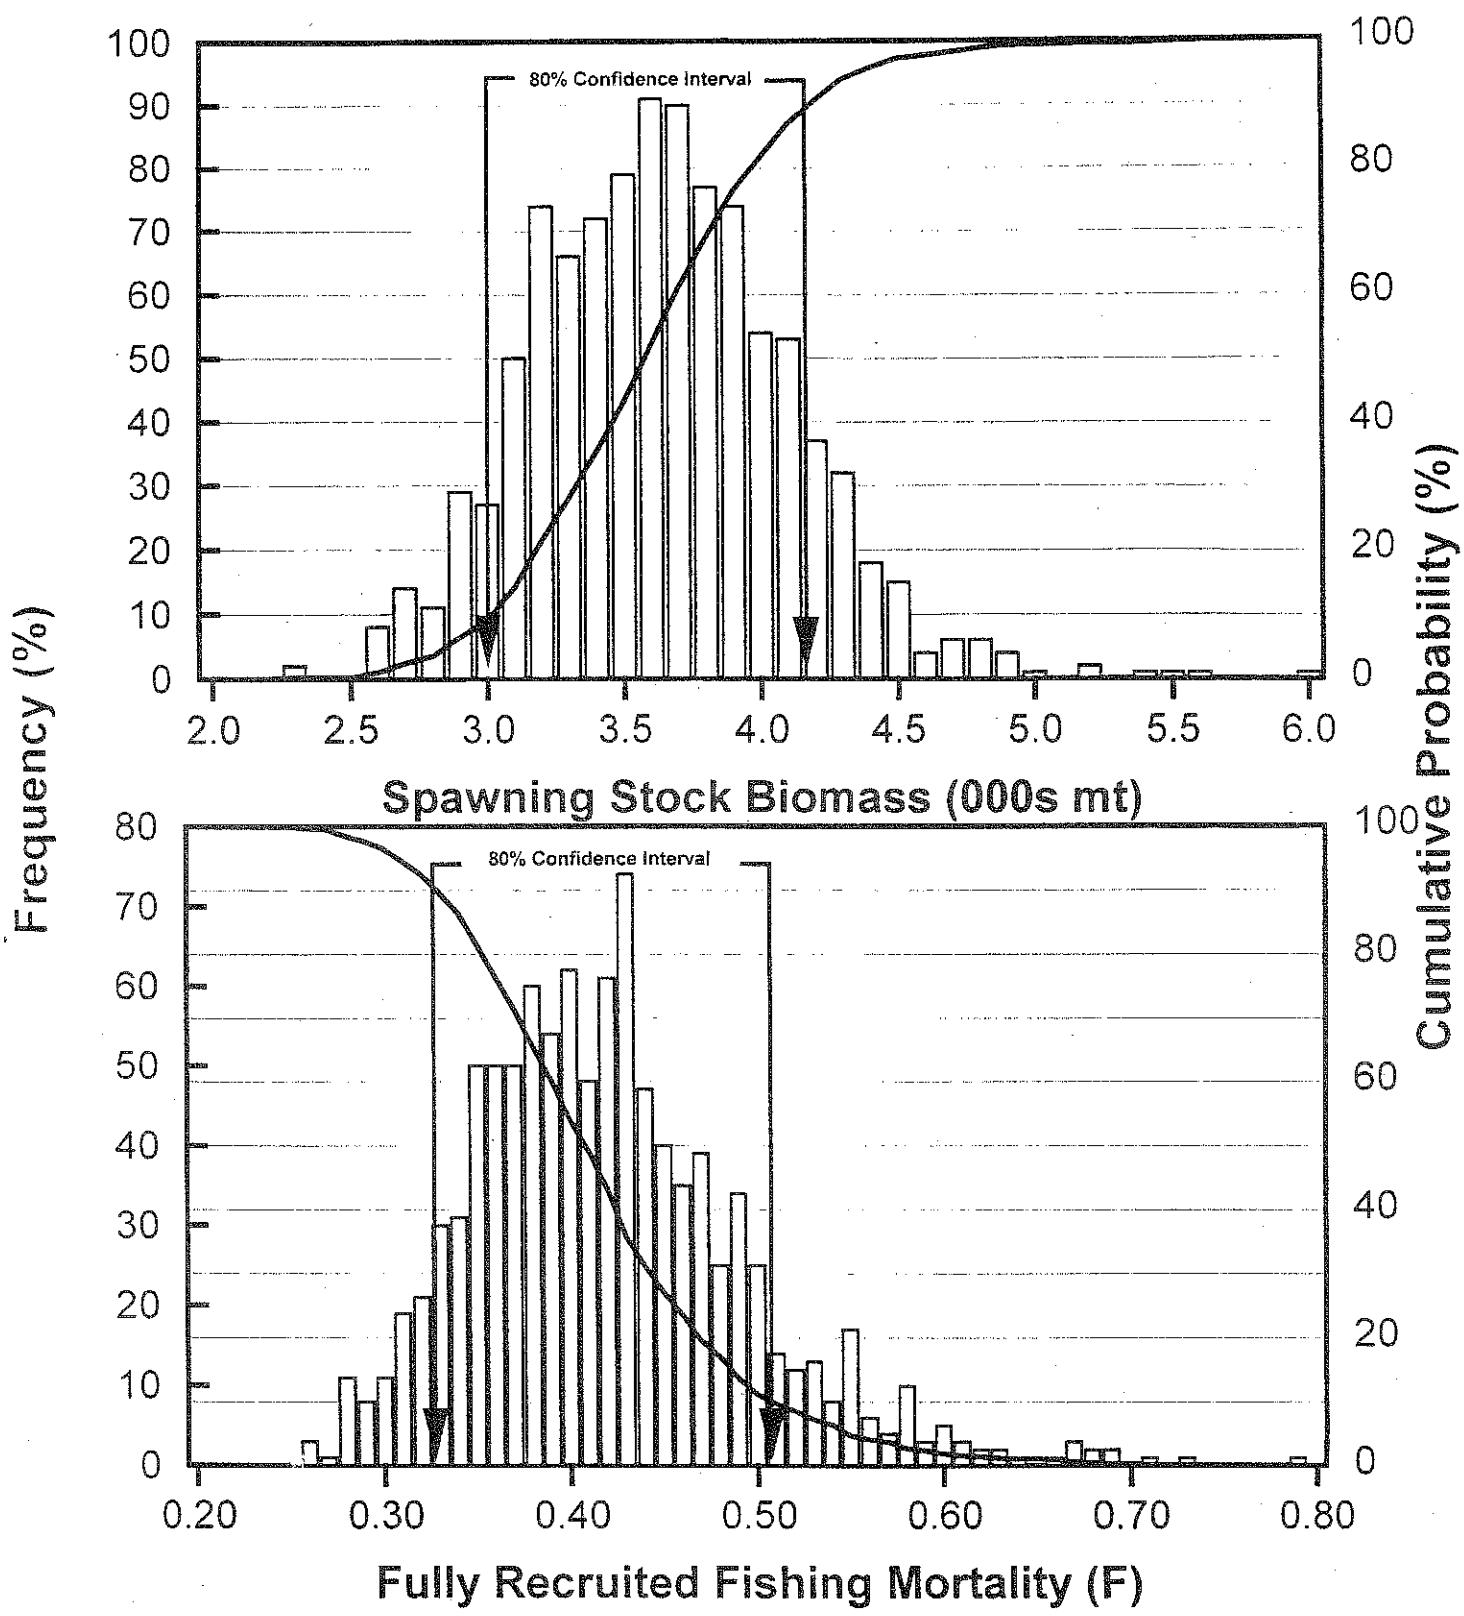

Figure 10. Precision of the estimates of spawning stock biomass (top panel) at the beginning of the spawning season (April 1) and instantaneous rate of fishing mortality (bottom panel) on the fully recruited ages (ages 4-6) in 1997 for Georges Bank winter flounder. The vertical bars display both the range of the estimator and the probability of individual values within the range. The solid line gives the probability of individual values within the range. The solid line gives the probability that F is greater than or SSB is less than the corresponding value on the X-axis. The solid arrows indicate the approximate 90% and 10% confidence levels for F and SSB. The precision estimates were derived from 1000 bootstrap replications of the final ADAPT VPA calibration.

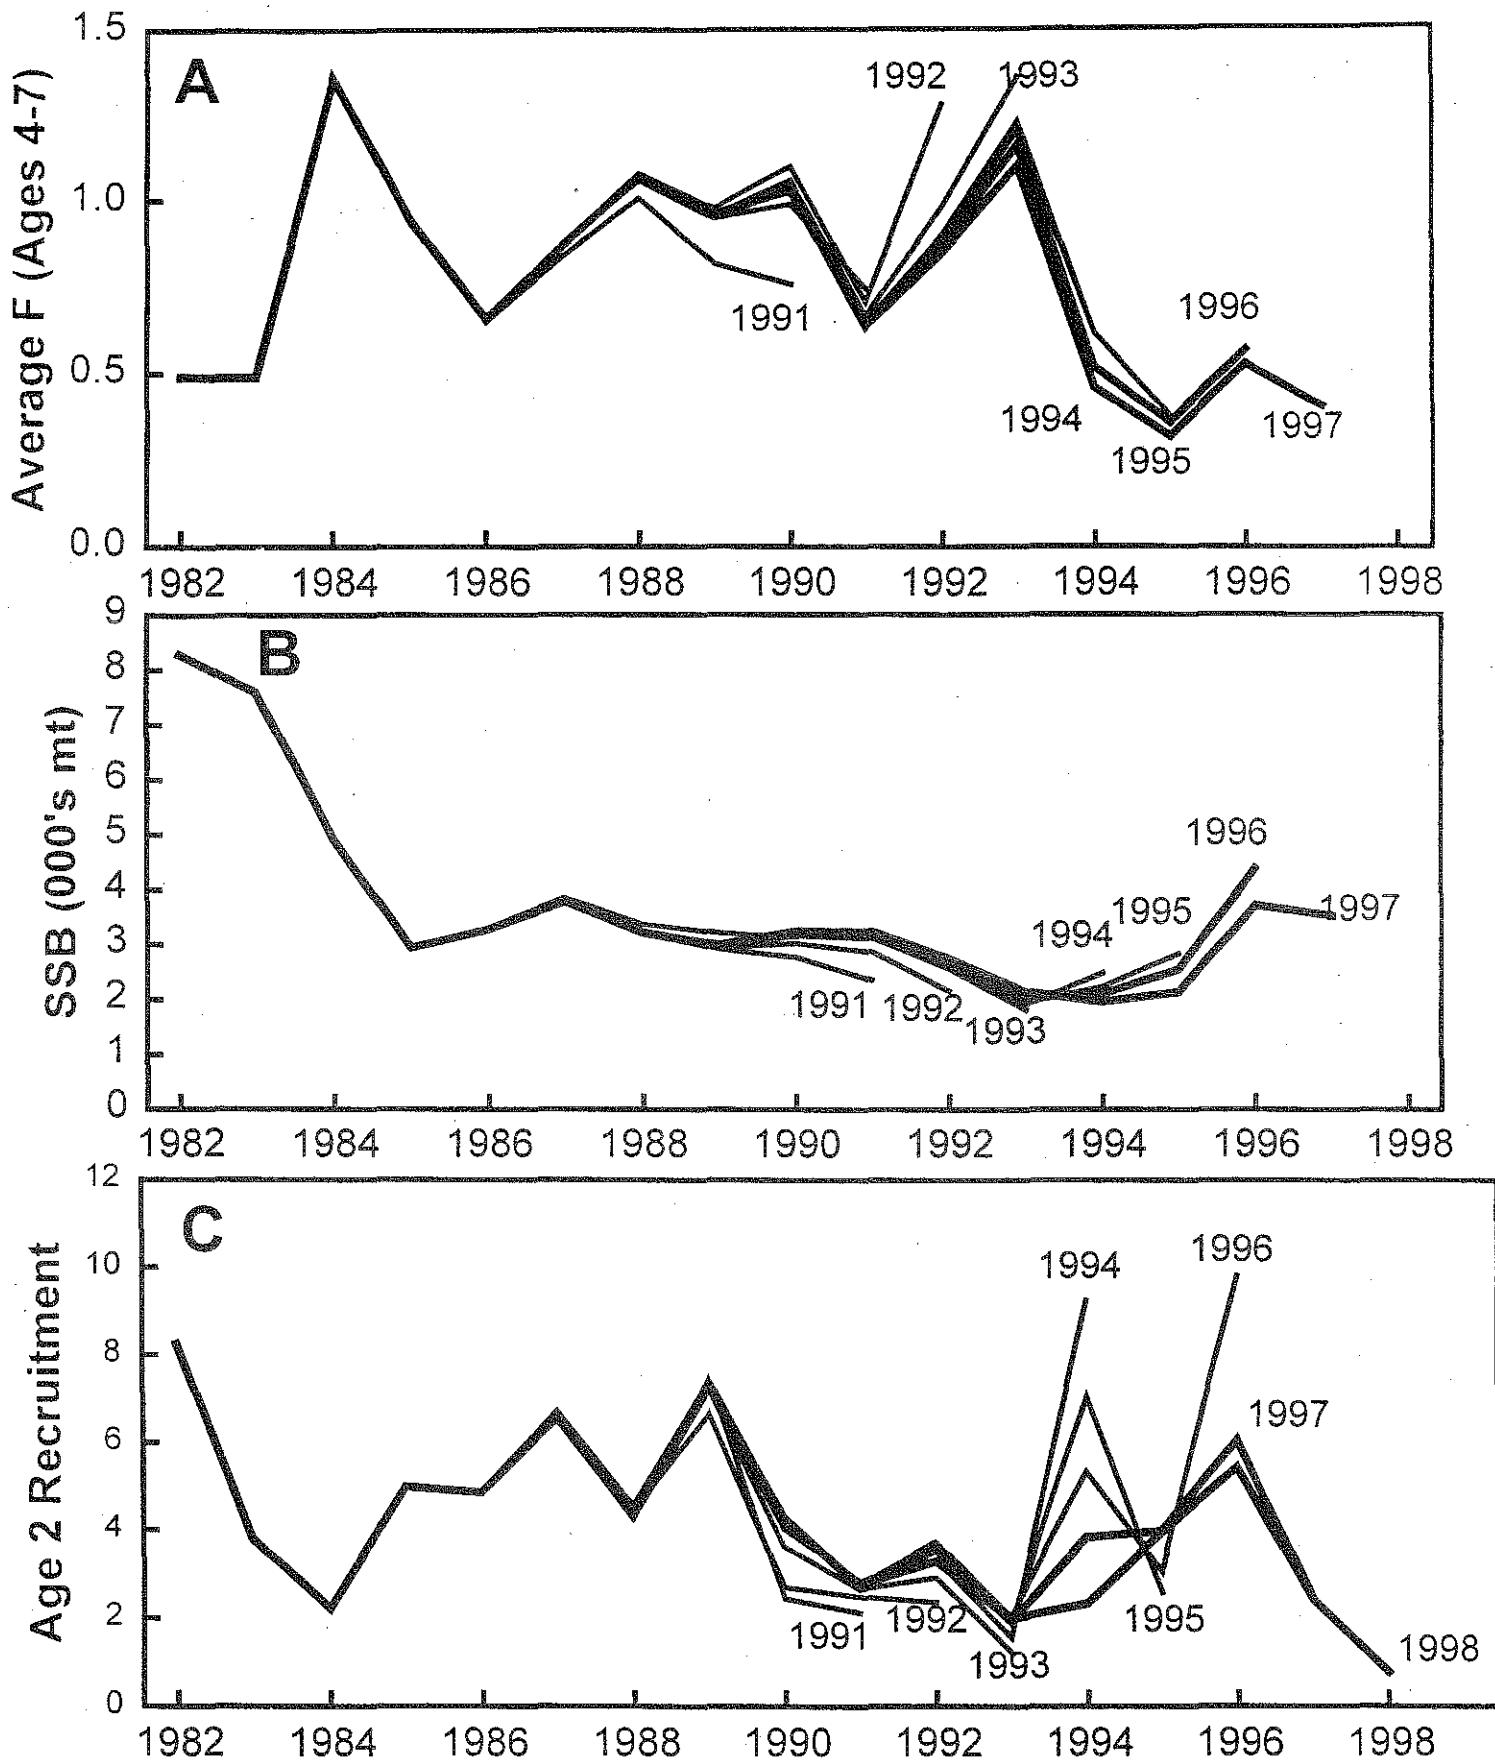

Figure 11. Retrospective analysis results of fishing mortality (Panel A), spawning stock biomass (Panel B), and age 2 recruitment (Panel C) for the Georges Bank winter flounder assessment, 1997-1990. 49

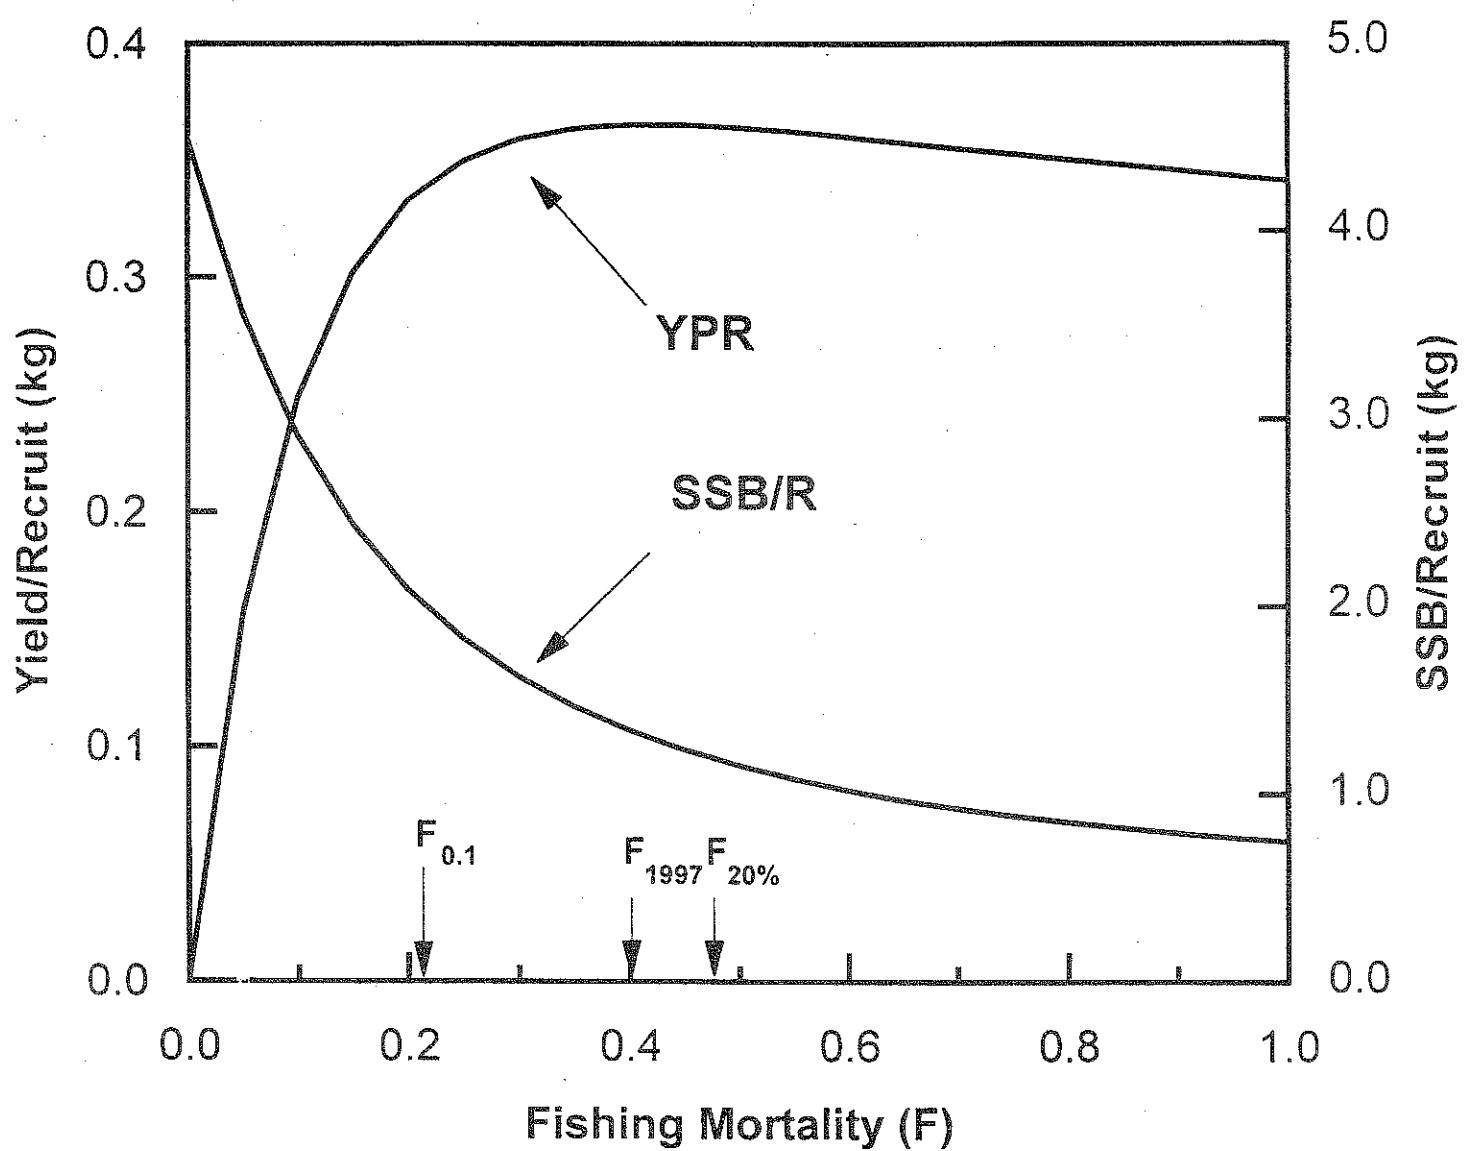

Figure 12. Yield (YPR) and spawning stock biomass (SSB/R) per recruit for Georges Bank winter flounder.

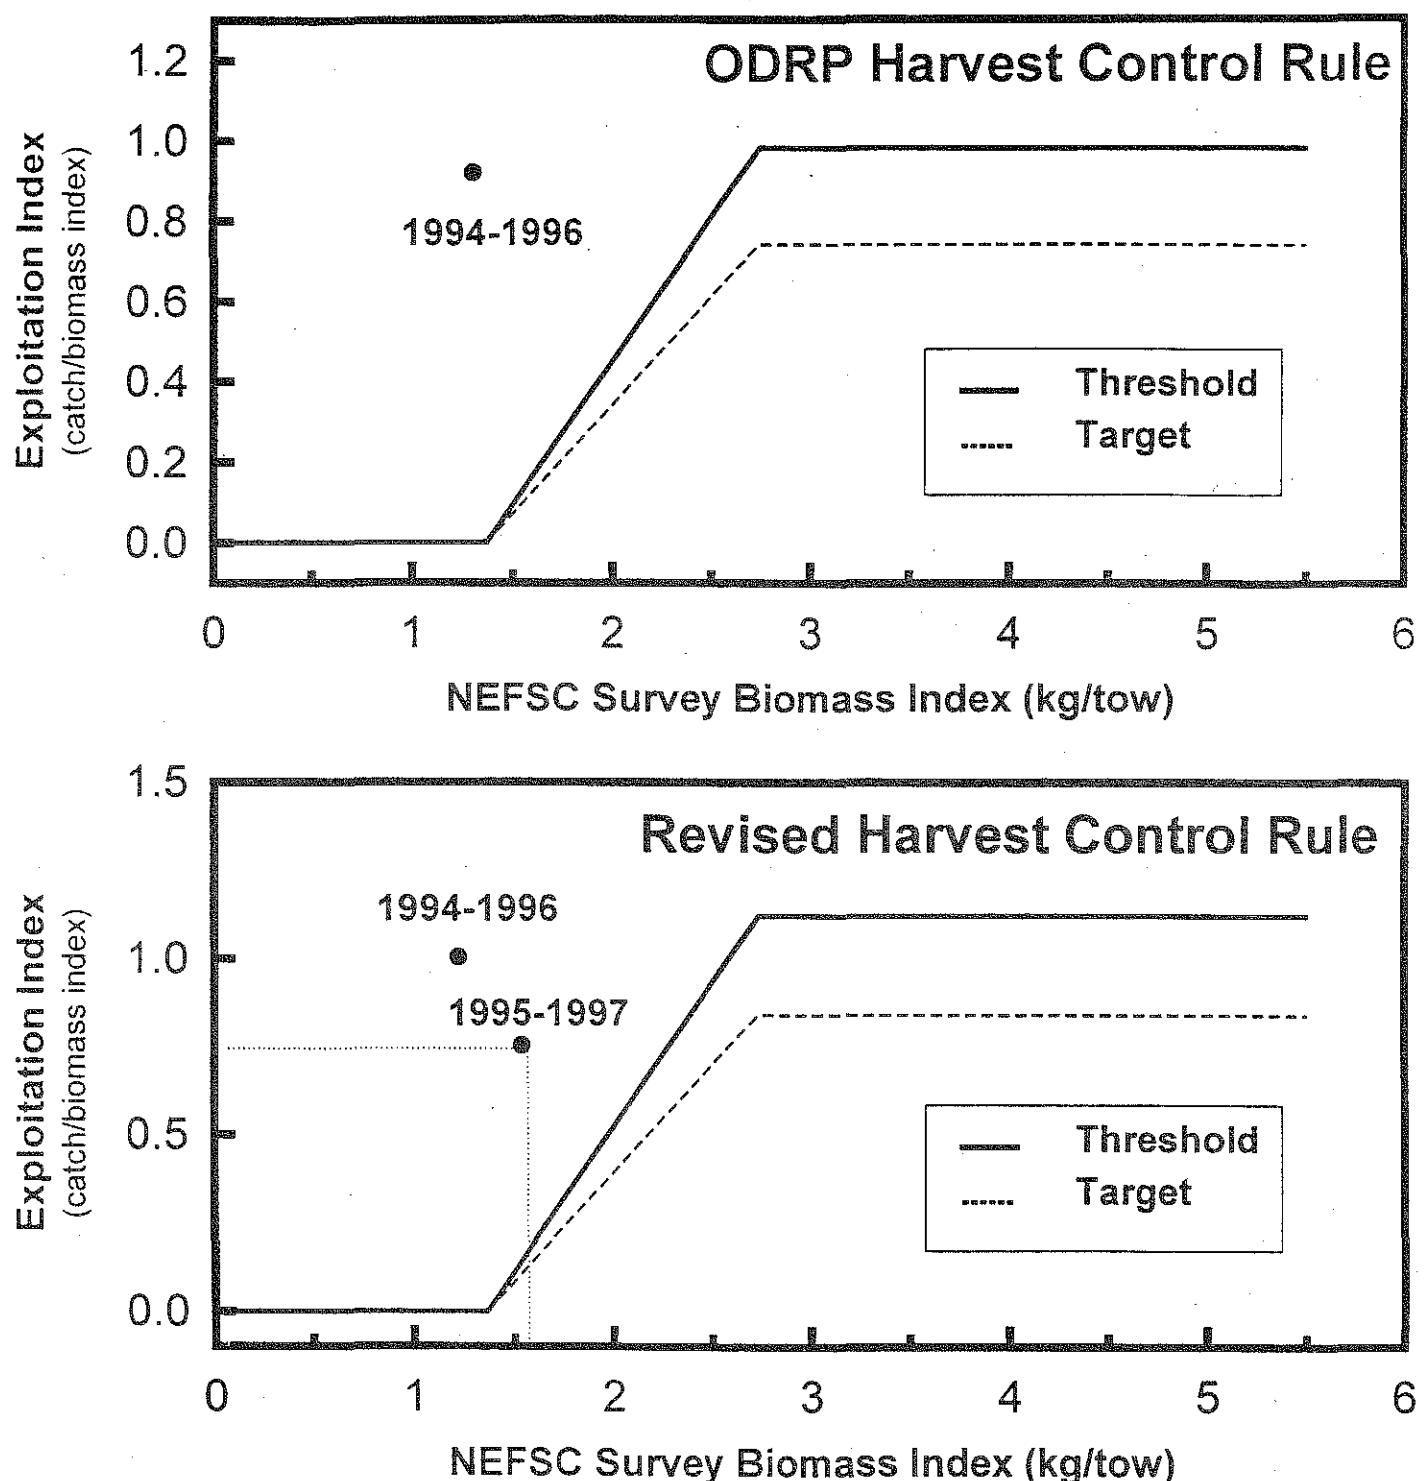

Figure 13. Proposed control rule for Georges Bank winter flounder based on survey equivalents of MSY-based reference points from the Overfishing Definition Review Panel report (Applegate et al. 1998).

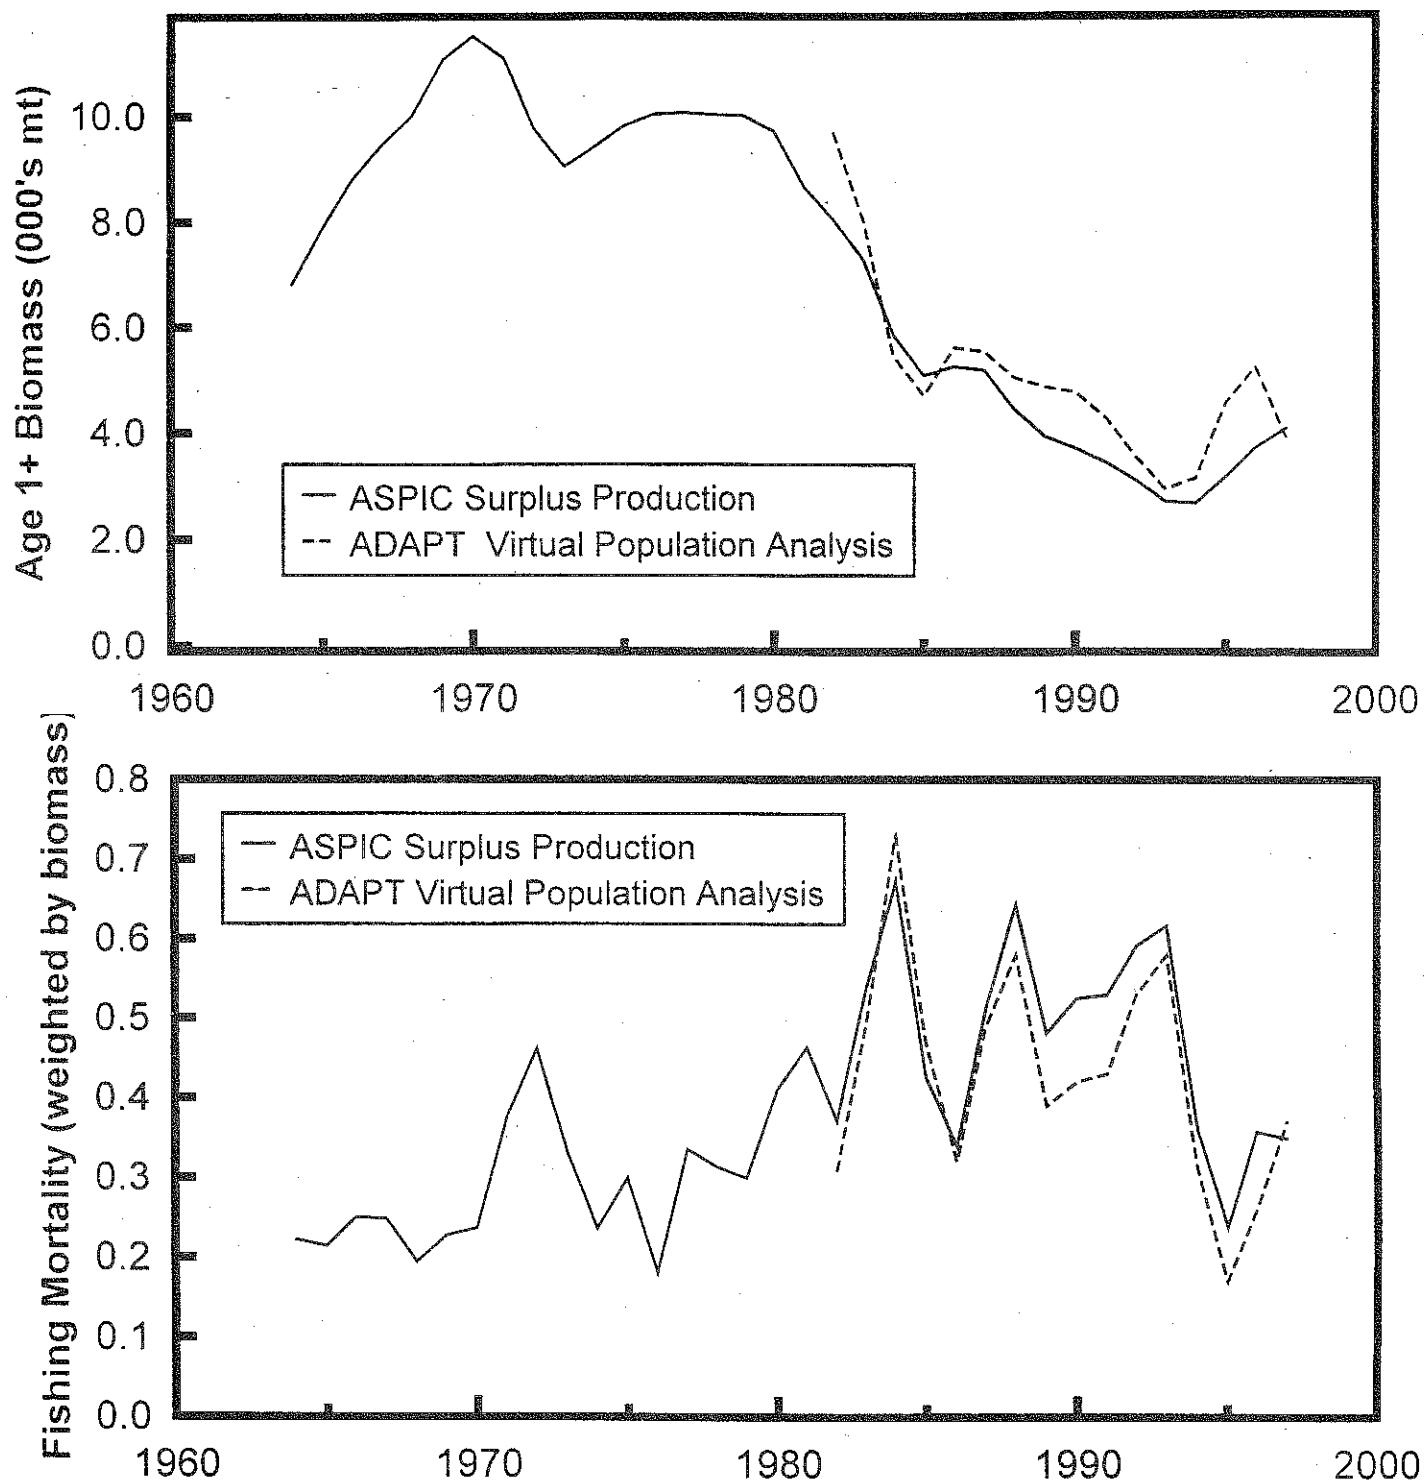

Figure 14. Comparison of estimated age 1+ biomass and fishing mortality (weighted by biomass) from an ASPIC surplus production model and an ADAPT virtual population analysis for Georges Bank winter flounder.

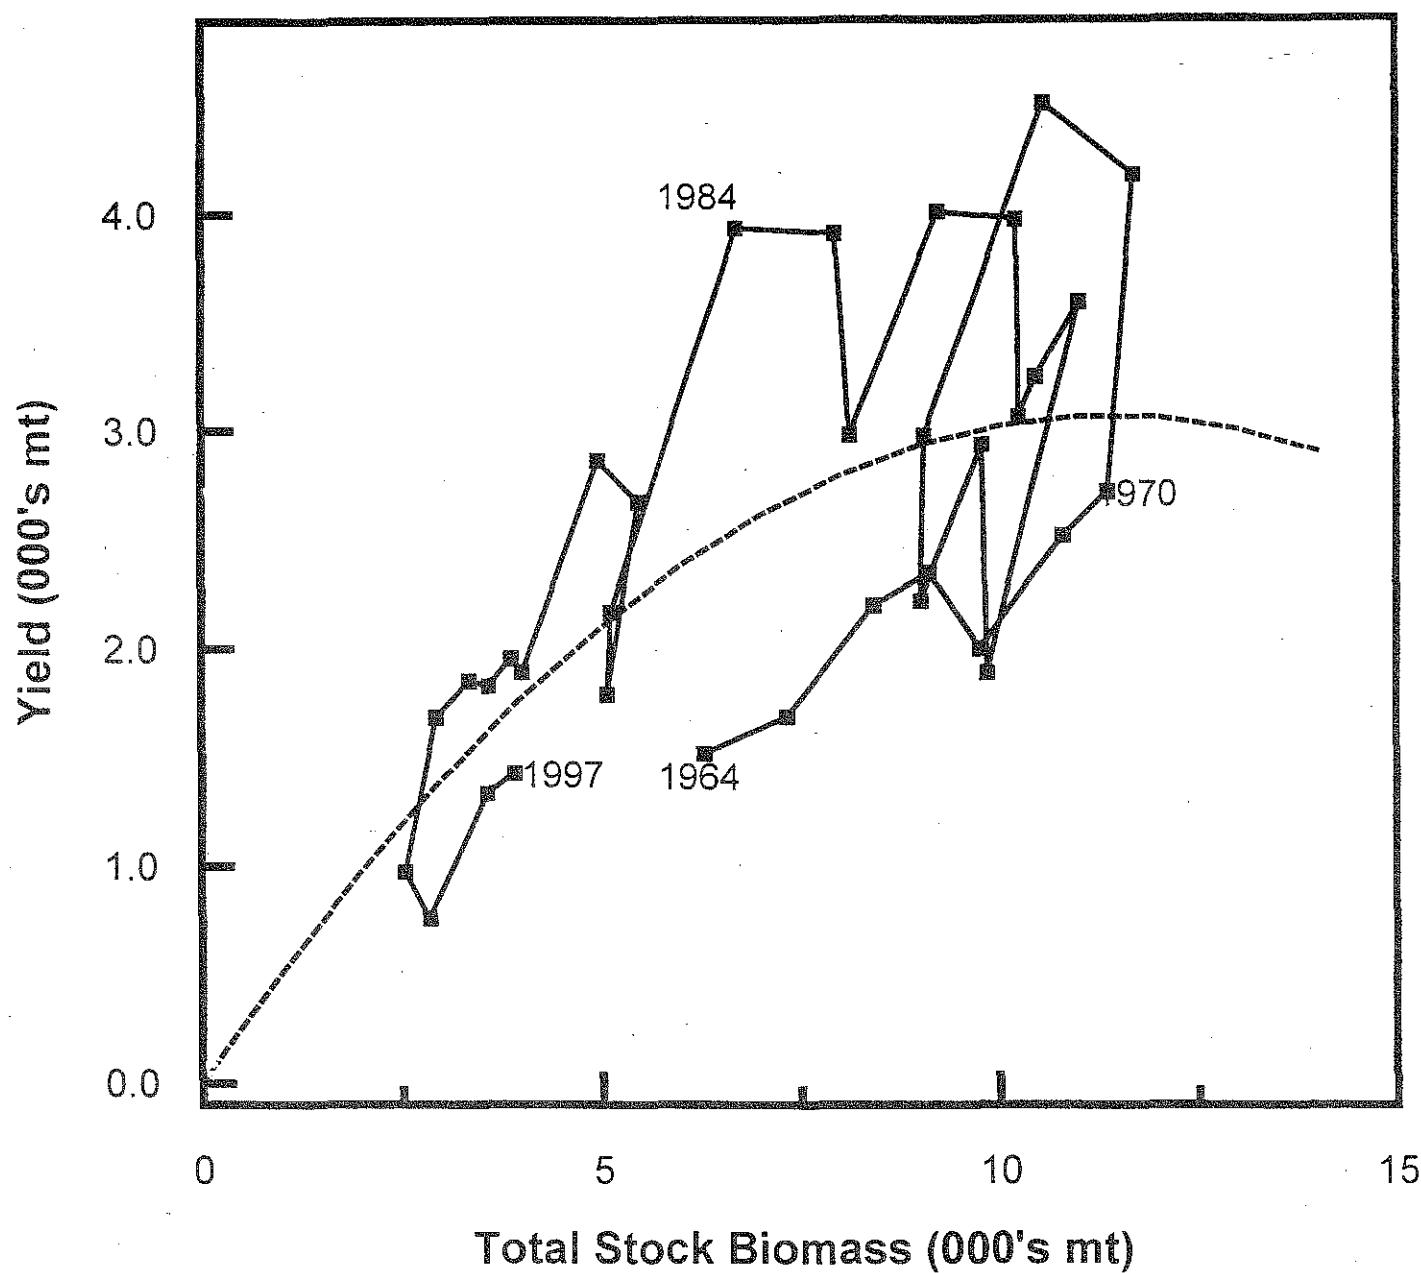

Figure 15. Time trajectory of fishery yield from the Georges Bank winter flounder stock relative to the surplus production curve estimated by ASPIC.

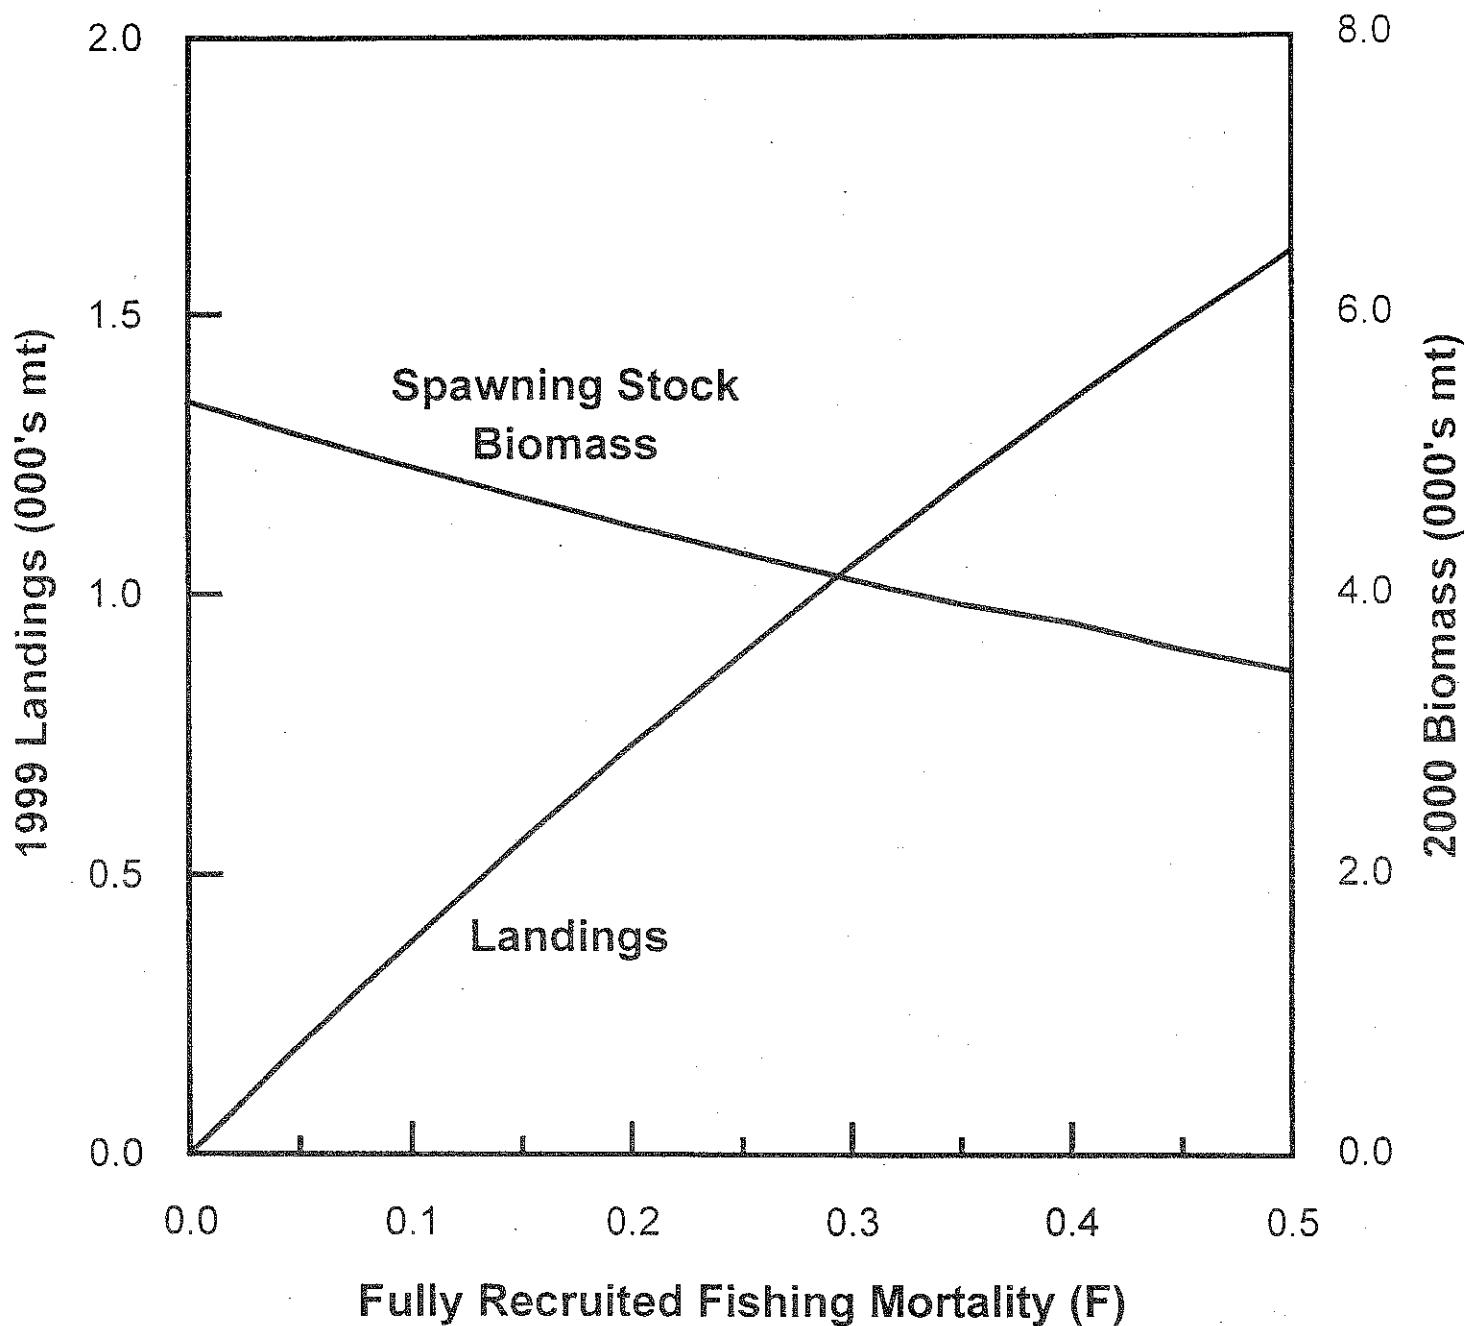

Figure 16. Results of short-term stochastic projections for the Georges Bank winter flounder stock. Projected landings of 1,107 mt assumed in 1998. Winter flounder landings in 1999 and spawning stock biomass in 2000 are shown as a function of fishing mortality in 2000.

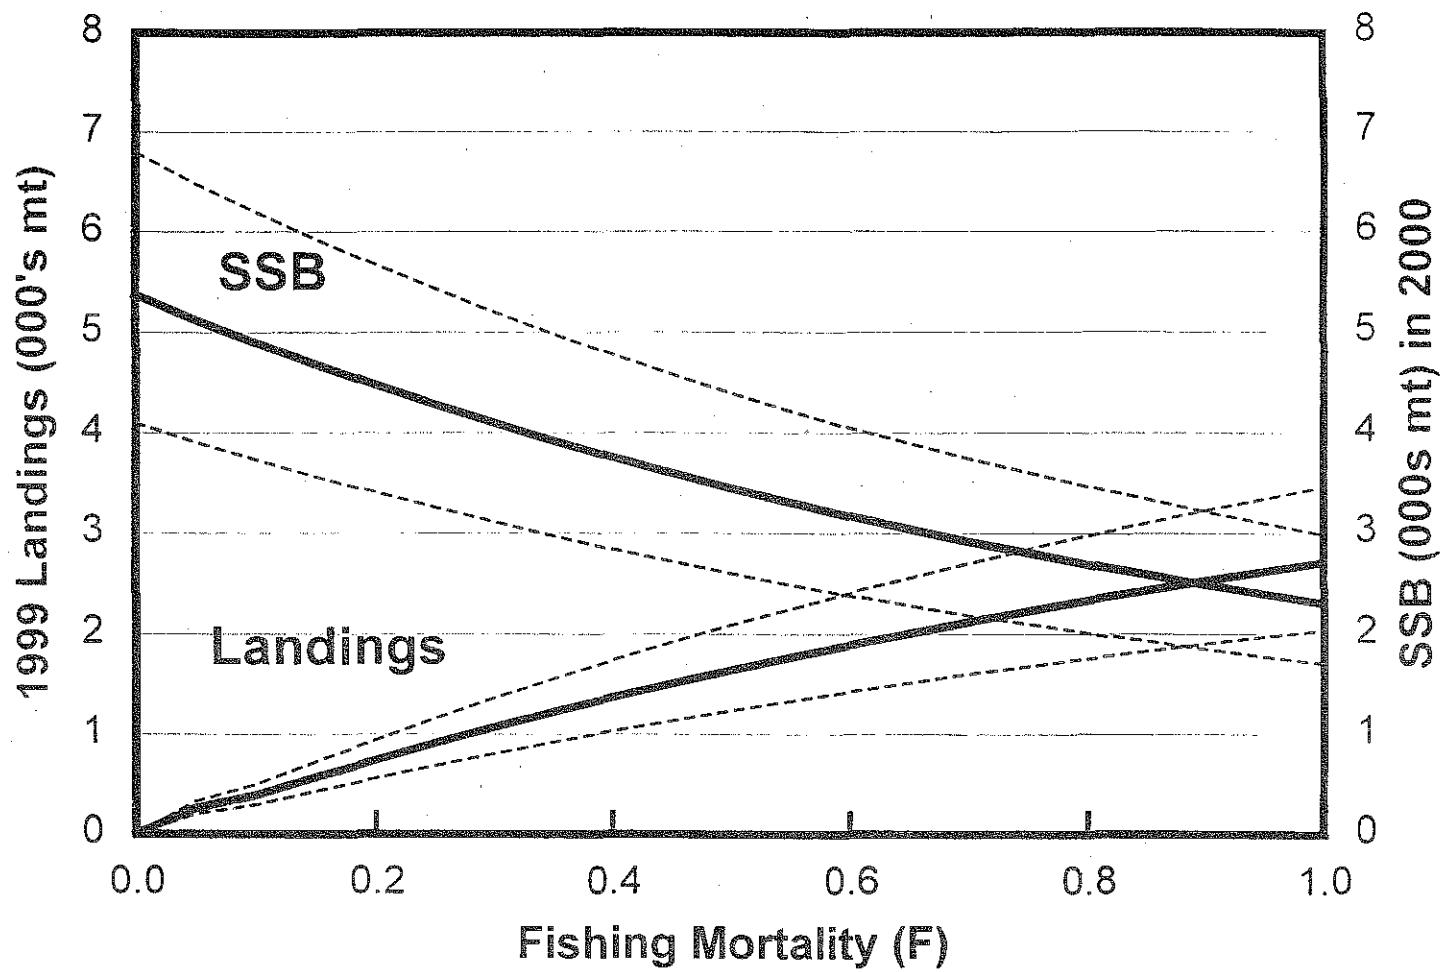

Figure 17. Results of short-term stochastic projections for the Georges Bank winter flounder stock. Projected landings of 964 mt assumed in 1998. Winter flounder landings in 1999 and spawning stock biomass in 2000 are shown as a function of fishing mortality in 1999. Dotted lines indicate 80% confidence intervals around each line.

Appendix 1. ADAPT VPA calibration for the Georges Bank winter flounder assessment.

Woods Hole Assessment Toolbox Georges Bank Winter Flounder 1982-1997 Run Number 15 11/15/98 3:09:38
Georges Bank Winter Flounder 1982-1997 1982 - 1998
Input Parameters and Options Selected

Natural mortality is 0.2
Oldest age (not in the plus group) is 6
For all years prior to the terminal year (1997), backcalculated
stock sizes for the following ages used to estimate
total mortality (Z) for age 6 : 4 5 6
This method for estimating F on the oldest age is generally used when a
flat-topped partial recruitment curve is thought to be characteristic of the stock.
F for age 7 + is then calculated from the following
ratios of F[age 7+] to F[age 6]

Stock size of the 7 + group is then calculated using
the following method: CATCH EQUATION

Partial recruitment estimate for 1998

1 0.01
2 0.2
3 0.6
4 1
5 1
6 1

Objective function is Sum w*(LOG(OBS)-LOG(PRED))**2

Indices normalized (by dividing by mean observed value)
before tuning to VPA stocksizes

Downweighting is not used

Biomass estimates (other than SSB) reflect mean stock sizes.
SSB calculated as in the NEFSC projection program
(see note below SSB table for description of the algorithm).
Initial estimates of parameters for the Marquardt algorithm

Tiburon, California 94920 USA

CONTROL PARAMETERS USED (FROM INPUT FILE)

Number of years analyzed:	34	Number of bootstrap trials:	0
Number of data series:	2	Lower bound on MSY:	1.000E+00
Objective function computed:	in EFFORT	Upper bound on MSY:	5.000E+02
Relative conv. criterion (simplex):	1.000E-08	Lower bound on r:	1.000E-01
Relative conv. criterion (restart):	3.000E-08	Upper bound on r:	1.000E-01
Relative conv. criterion (effort):	1.000E-04	Random number seed:	1964285
Maximum F allowed in fitting:	5.000	Monte Carlo search trials:	50000

PROGRAM STATUS INFORMATION (NON-BOOTSTRAPPED ANALYSIS)

code 0

Normal convergence.

CORRELATION AMONG INPUT SERIES EXPRESSED AS CPUE (NUMBER OF PAIRWISE OBSERVATIONS BELOW)

GOODNESS-OF-FIT AND WEIGHTING FOR NON-BOOTSTRAPPED ANALYSIS

Loss component number and title	Weighted SSE	N	Weighted MSE	Current weight	Suggested weight	R-squared in CPUE
Loss(-1) SSE in yield	0.000E+00					
Loss(0) Penalty for B1R > 2	0.000E+00	1	N/A	1.000E+00	N/A	
Loss(1) USA Fall Survey	1.037E+01	34	3.241E-01	1.000E+00	8.767E-01	0.295
Loss(2) USA Spring Survey	6.980E+00	30	2.493E-01	1.000E+00	1.140E+00	0.237

TOTAL OBJECTIVE FUNCTION: 1.73500742E+01

Number of restarts required for convergence: 4
Est. B-ratio coverage index (0 worst, 2 best): 0.9673
Est. B-ratio nearness index (0 worst, 1 best): 1.0000

MODEL PARAMETER ESTIMATES (NON-BOOTSTRAPPED)

Parameter	Estimate	Starting guess	Estimated	User guess
B1R Starting biomass ratio, year 1964	6.571E-01	1.000E+00	1	1
MSY Maximum sustainable yield	2.984E+00	2.500E+00	1	1
r Intrinsic rate of increase	6.566E-01	4.000E-01	1	1
..... Catchability coefficients by fishery:				
q(1) USA Fall Survey	2.410E-01	2.410E-01	0	1
q(2) USA Spring Survey	3.550E-01	3.550E-01	0	1

MANAGEMENT PARAMETER ESTIMATES (NON-BOOTSTRAPPED)

Parameter	Estimate	Formula
MSY Maximum sustainable yield	2.984E+00	Kr/4
K Maximum stock biomass	1.818E+01	
Bmsy Stock biomass at MSY	9.088E+00	K/2
Fmsy Fishing mortality at MSY	3.283E-01	r/2
F(0.1) Management benchmark	2.955E-01	0.9*Fmsy
Y(0.1) Equilibrium yield at F(0.1)	2.954E+00	0.99*MSY
B-ratio Ratio of B(1998) to Bmsy	6.627E-01	
F-ratio Ratio of F(1997) to Fmsy	7.945E-01	
Y-ratio Proportion of MSY avail in 1998	8.862E-01	2*Br-Br^2 Ye(1998) = 2.644E+00
..... Fishing effort at MSY in units of each fishery:		
fmsy(1) USA Fall Survey	1.362E+00	r/2q(1) f(0.1) = 1.226E+00
